territories of supply has been described. Damage to the anterior longitudinal artery can result in loss of function of the anterior two-thirds of the cord. The longitudinal arteries cannot supply the whole length of the cord, and the input of the segmental medullary feeder vessels is essential. This is especially true of the artery of Adamkiewicz (great anterior segmental medullary artery), which may effectively carry the major supply for the lower cord. The midthoracic cord, distant from the main anterior medullary feeders, is particularly liable to become ischaemic after periods of hypotension.
VEINS

The venous drainage of the spinal cord (Fig. 43.11) follows a similar pattern to that of its arterial supply (Gillilan 1970). Intramedullary veins within the substance of the cord drain into a plexus of surface veins, the coronal plexus. There are six tortuous longitudinal channels within this plexus, one in each of the anterior and posterior median fissures, and four others which run on either side of the ventral and dorsal nerve roots. Only the anterior median vein, which drains the central grey matter, is consistently complete. These vessels connect freely and drain superiorly into the cerebellar veins and cranial sinuses, and segmentally mainly into medullary veins. The segmental veins drain into the intervertebral veins and thence into the external vertebral venous plexuses, the caval and azygos systems.

Segmental veins

Anterior and posterior medullary veins run along some of the ventral and dorsal roots. They are larger than radicular veins, and drain the cord but not the roots themselves. Like the medullary feeder arteries, they are largest in the cervical and lumbar regions of the cord, but do not necessarily occur in the same segments as the medullary feeders. Anterior and posterior great medullary veins may arise in the lower thoracic
or upper lumbar cord segments. There are 8–14 anterior medullary veins; posterior medullary veins are more numerous.

Very small anterior and posterior radicular veins occur in most spinal segments, accompanying and draining the ventral and dorsal roots and some of the cord at the points of entry and exit of the rootlets: they usually drain into the intervertebral veins.
THE EFFECTS OF INJURY

SPINAL CORD INJURY AND VERTEBRAL COLUMN INJURY

In the assessment of a patient with spinal injury and neurological damage, it is important to remember that the level of cord and root injury will not coincide with that of the skeletal damage to the vertebral column.

In estimating the vertebral levels of cord segments in the adult, a useful approximation is that in the cervical region the tip of a vertebral spinous process corresponds to the succeeding cord segment (i.e. the sixth cervical spine is opposite the seventh spinal segment); at upper thoracic levels the tip of a vertebral spine corresponds to the cord two segments lower (i.e. the fourth spine is level with the sixth segment), and in the lower thoracic region there is a difference of three segments (i.e. the tenth thoracic spine is level with the first lumbar segment). The eleventh thoracic spine overlies the third lumbar segment and the twelfth is opposite the first sacral segment. In making this estimate by palpation of the vertebral spines, the relationship of the individual spines to their vertebral bodies should be remembered (p. 745).
Complete division above the fourth cervical segment causes respiratory failure because of the loss of activity in the phrenic and intercostal nerves. Lesions between C5 and T1 paralyse all four limbs (quadriplegia), the effects in the upper limbs varying with the site of injury: at the fifth cervical segment paralysis is complete; at the sixth, each arm is positioned in abduction and lateral rotation, with the elbow flexed and the forearm supinated, due to unopposed activity in the deltoid, supraspinatus, rhomboid and brachial flexors (all supplied by the fifth cervical spinal nerves). In lower cervical lesions upper limb paralysis is less marked. Lesions of the first thoracic segment paralyse small muscles in the hand and damage the sympathetic outflow to the head and neck, resulting in constriction of the pupil, recession of the eyeball, narrowing of the palpebral fissure and loss of sweating in the face and neck (Horner's syndrome). However, sensation is retained in areas innervated by segments above the lesion, thus cutaneous sensation is retained in the neck and chest down to the second intercostal space, because this area is innervated by the supraclavicular nerves (C3 and C4). At thoracic levels, division of the cord paralyses the trunk below the segmental level of the lesion, and both lower limbs (paraplegia). The first sacral neural segment is approximately level with the thoracolumbar vertebral junction: injury, which commonly occurs here, paralyses the urinary bladder, the rectum and muscles supplied by the sacral segments, and cutaneous sensibility is lost in the perineum, buttocks, the back of the thighs and the legs and soles of the feet. The roots of lumbar nerves descending to join the cauda equina may be damaged at this level, causing complete paralysis of both lower limbs. Lesions below the first lumbar vertebra may divide or damage the cauda equina, but severe nerve damage is uncommon and is usually confined to the spinal roots at the level of the trauma. Neurological symptoms
may also occur as a result of interference with the spinal blood supply, particularly in the lower thoracic and upper lumbar segments.

**Spinal cord injury without radiological abnormality: 'SCIWORA'

The spinal cord may be damaged without radiological evidence of skeletal injury in some injuries to the vertebral column. This is particularly liable to occur if the vertebral canal is abnormally narrowed, usually by osteoarthritic changes. In the elderly patient there may in addition be occlusive arterial disease, directly compromising an already precarious blood supply to the cord. This type of injury not uncommonly occurs in hyperextension injuries of the cervical spine in this age group. The cause of the damage may be direct injury to neural tissue by osteophytes or by an infolded ligamentum flavum, or direct or indirect injury to the vasculature of the cord. For cervical spinal injury, several cord syndromes have been described, relating the clinical picture to the anatomy of the neurological lesion within the cord. The commonest of these is central cord syndrome, which usually results from hyperextension injury to an osteoarthritic neck, in which the major injury is to the central grey matter. This gives a greater motor loss in the upper than in the lower limbs, with variable sensory loss. In anterior cord syndrome, which may occur in flexion–compression injuries of the neck, the damage occurs in the area of supply of the anterior spinal artery, sparing the posterior columns: the motor loss is usually proportionately greater in the lower than in the upper limbs, while sensory loss is less of a problem.
LESIONS OF THE SPINAL ROOTS, NERVES AND GANGLIA

Spinal roots, nerves and ganglia may be damaged in the vertebral and root canals and at the intervertebral foramina. Neurofibromas may occur on the roots and nerves in the root canals. As they enlarge these tumours become dumb-bell shaped, with both an intra- and an extra-spinal component in continuity: the clinical picture may thus include paradoxical features as the asymmetrical space-occupying lesion grows. Root compression usually presents acutely with pain which may be severe. The pain, paraesthesiae and numbness occur in a dermatomal distribution, and it may be difficult to demonstrate sensory loss on the trunk, because of dermatomal overlap. Severe traction injuries of the upper limbs may cause avulsion of spinal roots from the cord in the cervical region.

The anatomical basis for pain of spinal origin

In the diagnosis and description of pain of spinal origin it is particularly important to distinguish between radicular pain and somatic referred pain.

Radicular pain is caused by disorders that affect a spinal nerve or its dorsal root ganglion. This type of pain characteristically radiates, along a narrow band, into the area of the limb (or trunk wall) that the spinal nerve supplies, and is typically (although not always) lancinating in quality, not unlike an electric shock.

Referred pain is pain felt in the distribution of a nerve that is not the nerve that innervates the source of pain. Typically these nerves are derived from the same spinal cord segment. Referred pain is felt deeply, is typically aching in quality, and is felt across a broad area; although it may radiate into a limb (or around the trunk wall), it is typically constant in location. Patients may find it hard to define the outer boundaries of this pain, but they can clearly identify the centre of its distribution. Referred pain can be subdivided into somatic referred pain and visceral referred pain, according to its origin. Visceral referred pain is caused by disorders in viscera. In some instances, the referral can be quite remote from the viscus, as in cardiac pain that radiates into the neck. Somatic referred pain is caused by disorder of muscle and skeletal structures. Examples include lumbar spinal pain referred to the gluteal region, thigh, or leg; cervical spinal pain referred to the upper limb girdle; and cervical or thoracic spinal pain referred to the chest wall, where it can mimic cardiac pain. Often the source of somatic referred pain cannot be determined by clinical examination, and requires invasive tests to pinpoint its location.
Lesions of the conus and cauda equina, e.g. tumours, cause bilateral deficit, often with pain in the back extending into the sacral segments and to the legs. Loss of bladder and erectile function can be early features. There are lower motor neurone signs in the legs with fasciculation and muscle atrophy. Sensory loss usually involves the perineal or ‘saddle area’ as well as involving other lumbar and sacral dermatomes. There may be congenital abnormalities, e.g. spina bifida, lipomata or dysraphism, and the conus may extend below the lower border of L1, often with a tethered filum terminale. Extramedullary lesions include prolapsed intervertebral discs. A midline (central) disc protrusion in the lumbar region may present with involvement of only the sacral segments.
CLINICAL PROCEDURES

ACCESS TO CEREBROSPINAL FLUID

The safest approach to the cerebrospinal fluid (CSF) is to enter the lumbar cistern of the subarachnoid space in the midline, well below the level at which the spinal cord normally terminates (see above). The fine needle employed is unlikely to damage the mobile nerve roots of the cauda equina. This procedure is called lumbar puncture. It is also possible to access the CSF by midline puncture of the cerebello-medullary cistern (cisterna magna) (Ch. 16): this is cisternal puncture.

Lumbar puncture: adult

Lumbar puncture in the adult may be performed with the patient either sitting or lying on the side on a firm flat surface. In each position, the lumbar spine must be flexed as far as possible, in order to separate the vertebral spines maximally and expose the ligamentum flavum in the interlaminar window (Fig. 43.12). A line is then taken between the highest points of the iliac crests: this line intersects the vertebral column just above the palpable spine of L4. With the spines now identified, the skin is anaesthetized and a needle is inserted between the spines of L3 and L4 (or L4 and L5). Exact identification of the level by palpation is difficult (Broadbent et al 2000). The soft tissues which the needle will ultimately traverse should also be anaesthetized, though care should be taken lest the injection of an excessive amount of local anaesthetic compromises appreciation of the structures being traversed. These include the subcutaneous fat, and supraspinous and interspinous ligaments down to the ligamentum flavum itself. The lumbar puncture needle may then be inserted in the midline or just to one side, and angled in the horizontal and sagittal planes sufficiently to pierce the ligamentum flavum in or very near the midline. There is then a slight loss of resistance as the needle enters the epidural space, and careful advancement will next pierce the dura and arachnoid to release CSF.
Lumbar puncture: neonate and infant

At full term (40 weeks) the spinal cord usually terminates somewhat lower than the adult level, sometimes reaching the body of L3. The supracristal plane intersects the vertebral column slightly higher (L3–4). By the second postnatal month the level of cord termination has usually reached its permanent position level with the body of the first lumbar vertebra. The lower
end of the subarachnoid spine is found at sacral levels 1 or 2. These differences must be borne in mind when identifying the landmarks before undertaking lumbar puncture in the neonate and infant.

A lumbar puncture is performed by placing the baby in a position, either lying or 'sitting', which gives maximum convex curvature to the lumbar spine. A needle with trocar is inserted into the back between the spines of the third and fourth lumbar vertebrae and into the subarachnoid space below the level of the conus medullaris. The space between L3 and L4 is approximately level with the iliac crests and it is usual to insert the needle and trocar into the intervertebral space immediately above or below the iliac crests.

Cisternal puncture

In cisternal puncture, the cisterna magna (Ch. 16) is entered by midline puncture through the posterior atlanto-occipital membrane. Further details of this difficult specialist technique are beyond the scope of this book.
ACCESS TO THE EPIDURAL SPACE

The epidural space lies between the spinal dura and the wall of the vertebral canal. It contains epidural fat and a venous plexus. Access to this space, usually in the lumbar region, is required for the administration of anaesthetic and analgesic drugs, and for endoscopy. The caudal route is used mainly for analgesic injections.

Thoracic and cervical epidurals

It is possible to access the epidural space at thoracic and cervical levels, but the specialist techniques required are outside the scope of this book. The principles are the same as those for lumbar epidurals, but the special anatomy of the vertebral spines at the other levels requires the angle of approach to be modified.

Lumbar epidural

For access to the lumbar epidural space, the approach is as for lumbar puncture. The intention in epidural injection is to avoid dural puncture, so it is best to enter the epidural space in the midline posteriorly, where the depth of the space is greatest. Techniques for entering the epidural space rely on the appreciation of loss of resistance to injection of the chosen medium (usually air or saline) as the space is entered. This loss of resistance results from the fact that the pressure in the epidural space is subatmospheric. There is very little distance between the ligamentum flavum and the underlying dura on either side of the median plane.

Caudal epidural

The route of access to the caudal epidural space is via the sacral hiatus. The space is therefore entered below the level of termination of the dural sac, i.e. the subarachnoid space and its contained CSF, which usually extends to the level of the second sacral segment. Occasionally the dural sac ends as high as the fifth lumbar vertebra, and very rarely it may extend to the third part of the sacrum, in which case it is occasionally possible to enter the subarachnoid space inadvertently during the course of a sacral nerve block.

With the patient in the lateral position or lying prone over a pelvic pillow, the sacral hiatus is identified by palpation of the sacral cornua (Fig. 43.13). These are felt at the upper end of the natal cleft approximately 5 cm above the tip of the coccyx. Alternatively, the sacral hiatus may be identified by constructing an equilateral triangle based on a line joining the posterior superior iliac spines: the inferior apex of this triangle overlies the hiatus. After local anaesthetic infiltration, a needle is introduced at 45° to the skin, to penetrate the posterior sacrococcygeal ligament and enter the sacral canal. Once the canal is entered, the hub of the needle is lowered so that the needle may pass along the canal (Fig. 43.2, Fig. 43.14). If the needle is angled too obliquely it will strike bone; if it is placed too superficially it will lie outside the canal. The latter malposition can be confirmed by careful injection of air while palpating the skin over the lower sacrum.

CHAPTER 44 – Development of the back

Vertebrae and their alternating intervertebral discs are one of the main manifestations of body segmentation or metamерism. A chain of segments arranged in sequence allows the overall structure to bend when it is moved by the associated muscles. The original body segments, the somites, are formed by the paraxial mesenchyme which is found lateral to the neural tube and notochord in the early embryo. The somites provide the embryonic cell populations for bone and muscle. The vertebrae form between the early body segments by the recombination of portions of the somites on the craniocaudal axis, and the muscles attach to adjacent vertebrae. Each vertebra develops from bilateral origins to form a midline centrum, two lateral arches bearing transverse processes which develop lateral and dorsal to the spinal cord, and a midline fused dorsal portion with a spinous process. Individual vertebrae may be distinguished by modifications of these component parts. The intervertebral discs develop from the same origins as the centra, and are composed of outer dense fibrous tissue surrounding a softer central zone.

SEGMENTATION OF PARAXIAL MESENCHYME

Epiblast cells which ingress through the lateral aspect of the primitive node and the rostral primitive streak (see Fig. 10.3) become committed to a somitic lineage (see p. 184). After passing through the streak the cells retain contact with both the epiblast and hypoblast basal laminae as they migrate and for some time after reaching their destination. The cells form populations of paraxial mesenchyme on each side of the notochord, termed presomitic or unsegmented mesenchyme. Somites will form from cultured presomitic mesenchyme with or without the presence of neural tube tissue or primitive node tissue. As well as specifying somitic lineage, the position of ingression of the epiblast informs the specific destination of the cells. Thus those cells which ingress through the lateral portion of Hensen’s node form the medial halves of the somites, whereas those ingressing through the primitive streak approximately 200 µm caudal to the node produce the lateral halves of the somites. The two somite halves do not appear to intermingle.

The segmentation of the paraxial presomitic mesenchyme occurs as a sequential process along the craniocaudal axis. In some amniote embryos a pair of somites is formed every 90 minutes until the full number is obtained. The molecular pathway for this synchronous segmentation has been termed the segmentation clock. It has been identified as a conserved process in vertebrates from fish to mammals, and is based on the rhythmic production of mRNAs for the transcription of genes related to Notch, a large transmembrane receptor, and a number of transmembrane ligands.

Intrinsically coordinated pulses of mRNA expression appear as a wave within
the presomitic mesenchyme as each somite forms. As new cells enter the
paraxial mesenchyme caudally they begin phases of up-regulation of the
cycling genes followed by downregulation of these genes. During each cycle
the most cranial presomitic mesenchyme will segment to form the next
somite.

Experimental evidence (from chick embryos) shows that newly formed
paraxial mesenchyme cells undergo 12 such cycles before they finally form a
somite (Pourquie & Kusumi 2001). Thus from ingression through the primitive
streak to segmentation into a somite takes approximately 18 hours. As the
somite number varies between vertebrate species, it is likely that the rate of
somite formation also varies and may be longer in human embryos. Indeed
those vertebrates with elongated bodies and many somites appear to form
somites more rapidly than those with shorter bodies, a finding which supports
the concept that somite number is controlled in part by species-specific
cyclical properties of the presomitic mesenchyme (Richardson et al 1998).

The final determination of somitic boundary formation has not yet been fully
elucidated, but seems to require a periodic repression of the Notch pathway
genes. The caudal presomitic mesenchyme cells are thought to be
maintained in an immature state by their production of FGF8. The cells
become competent for segmentation when FGF8 levels drop below a certain
threshold. They would then be in close apposition to cells that have
segmented (i.e. the next cranial somite).

This area of research is moving rapidly. A detailed critique of the conceptual
models of segmentation is given by Stern & Vasiliaskas (2000). An overview
of the processes involved in the development of the paraxial mesenchyme,
based on the work of Christ et al (2000), is shown in Figure 44.1.
Fig. 44.1 Processes in the development of the paraxial mesenchyme in the avian embryo. Signals are indicated by open arrows; genes are italicized.

SOMITOCYTOGENESIS

Somitogenesis is a process in which five main stages can be identified (Figs 44.2, 44.3). Compaction and formation of the spherical epithelial somite surrounding free somitocele cells occur prior to segmentation of the paraxial mesenchyme. Once the somite boundaries have been defined there is an epithelial/mesenchymal transition of the ventral and ventromedial walls of the somite to form the sclerotome. This is followed by bilateral movement of these ventral and medial mesenchyme populations around the notochord and the neural tube. The final stage is formation of the epithelial plate of the somite, also termed the dermomyotome, from the remaining somitic epithelium. Segmentation of the paraxial mesenchyme, formation of somites and resultant somitogenetic processes occur in a craniocaudal progression caudal to the otic vesicle from stage 9.

![Fig. 44.2](image) Scanning electron micrograph of a lateral view of an embryo showing the somites. The cranial somites are at the upper border and the more caudal somites are at the lower border. A change in size of the cranially more advanced
The Golgi apparatus, and actin and α-actinin are all located in the apical region of the epithelial somite cells. Cilia develop on the free surface. The cells are joined by tight junctions (a variety of cell adhesion molecules has been demonstrated in epithelial somites). The basal surface rests on a basal lamina which contains collagen, laminin, fibronectin and cytotactin. Processes from the somite cells pass through this basal lamina to contact the basal laminae of the neural tube and notochord. Dorsoventral patterning of the putative vertebral column is dependent on the interaction of SHH from the notochord/floor plate with Wnt1 and Wnt3a from the roof plate and Wnt6 from the overlying ectoderm.

The epithelial somite undergoes rapid development (Fig. 44.3). The cells of the...
ventromedial wall which were abutting the neural tube undergo an epithelial/mesenchyme transformation and break apart. The newly formed mesenchymal cells, which are collectively termed the sclerotome, proliferate. The remaining cells of the somite are now termed the epithelial plate of the somite (or dermomyotome). This epithelium is proliferative; it produces the cell lines which will give rise to (nearly) all the striated muscles of the body.

The sclerotomal population has been subdivided in the chick and the fates of the cells followed (Christ, Huang & Scaal 2004) (Fig. 44.4–44.6). The main mass of the sclerotome is termed the central sclerotome, that portion close to the notochord is termed the ventral sclerotome, and the portions adjacent to the dermomyotome are termed dorsal sclerotome and lateral sclerotome. The central sclerotome remains close to the dermomyotome; it will give rise to the pedicles and ventral parts of the neural arches, and the proximal ribs. The ventral sclerotomal cells, which were always lateral to the notochord, proliferate to form an axial cell population within the extracellular matrix of the perinotochordal space, now termed the perinotochordal sheath. The dorsal sclerotomal cells develop relatively late and invade the space between the surface ectoderm and growing neural tube and form the dorsal part of the neural arches. The lateral sclerotomal cells give rise to distal ribs and endothelial cells of blood vessels. Generally there is a dorsolateral expansion of the whole sclerotome rather than the medial migration of a population of sclerotomal cells (Gasser 2006). This can be seen in Figures 44.4–44.6. Sclerotomal cells also give rise to the meninges surrounding the spinal cord, local tendons and ligaments. The somitocele cells which remain mesenchymal throughout somite formation give rise to the vertebral joints, intervertebral discs and the proximal ribs (Christ, Huang & Scaal 2004).

The dermomyotome is a proliferative epithelium which produces cells from four borders (Fig. 44.7). Proliferation at the dorsomedial edge produces cells from the cranial to the caudal edge of the dermomyotome; they elongate beneath its basal lamina as they move laterally. Cells similarly proliferate from the cranial and caudal edges of the dermomyotome and these cells also elongate across it. The cells that are produced from these three edges are collectively termed the myotome, and will give
rise to skeletal muscle dorsal to the vertebrae, i.e. the epaxial musculature. At limb levels cells de-epithelialize and migrate from the ventrolateral edges of the dermomyotome into the limb bud. Cells produced from this portion of the occipital somites migrate anteriorly to give rise to the intrinsic muscles of the tongue. At interlimb levels a hypaxial proliferation of myogenic cells that will give rise to intercostal and abdominal muscles extends from the ventrolateral edge of the epithelial dermomyotome into the body wall as development proceeds (Scaal & Christ 2004).

Fig. 44.7 A–D, Epaxial and hypaxial muscle origin from the dermomyotome. A, Early dermomyotome proliferation. B, Dermomyotome at interlimb level producing expaxial myoblasts. C, Dermomyotome at limb level. Hypaxial dermomyotome cells de-epithelialize from the ventrolateral edge and migrate into the limb bud. D, Local dermis is formed later by superficial de-epithelialization of dermomyotome cells.

It was thought that the somite gave rise to segmental portions of the dermis of the skin as well as bone and muscle. However, it is now clear that the somitic contribution to the skin from the epithelial plate is limited to de-epithelialization of dermomyotome cells over the epaxial muscles alone, which is a much smaller distribution than the segmental portion of skin usually implied by the term dermatome. The concept that an embryological dermatome, derived from the somite, produces all of the dermis of the skin is therefore outdated.

The regularity of somite formation provides criteria for staging embryos. The staging scheme proposed by Ordahl (1993) will be used in the following account of relative somite development. Ordahl noted that morphogenetic events occur in successive somites at approximately the same rate. The somite most recently formed from the unsegmented mesenchyme is designated as stage I, the next most recent as stage II, etc. After the embryo forms an additional somite, the ages of the previously formed somites increase by one Roman numeral. According to this scheme, compaction occurs at stage I; epithelialization at stages II to III; formation of mesenchymal sclerotome cells from stage V; myotome formation at stage VI; early migration of the ventrolateral lip of the epithelial plate and production of myotome cells are still occurring at stage X.
DEVELOPMENT OF SCLEROTOMES

Sclerotomal populations form from the ventral half of the epithelial somite. An intrasegmental boundary (fissure or cleft, sometimes termed von Ebner's fissure) that is initially filled with extracellular matrix and a few cells, appears within the sclerotome and divides it into loosely packed cranial and densely packed caudal halves. The epithelial plate, and later the dermomyotome, spans the two half-sclerotomes. The bilateral sclerotomal cell populations migrate towards the notochord and surround it to form the perinotochordal sheath. They undergo a matrix-mediated interaction with the notochord, differentiating chondrogenetically to form the cartilaginous precursor of the vertebral centrum. The perinotochordal sheath transiently expresses type II collagen, and this is believed to initiate type II collagen expression, and thereafter a chondrogenic fate, in those mesenchyme cells which contact it. Each vertebra is formed by the combination of much of the caudal half of one bilateral pair of sclerotomes with much of the cranial half of the next caudal pair of sclerotomes. Their fusion around the notochord produces the blastemal centrum of the vertebra (Figs 44.8 and 44.9). The mesenchyme adjoining the intrasegmental sclerotomic fissure now increases greatly in density to form a well-defined perichordal disc which intervenes between the centra of two adjacent vertebrae and is the future anulus fibrosus of the intervertebral symphysis ('disc') (see below).

Fig. 44.8 Formation of vertebrae and intervertebral discs from the mesenchymal sclerotomes. Each vertebra is formed from the cranial half of one bilateral pair of sclerotomes and the caudal half of the next pair of sclerotomes.
Fig. 44.9  Contribution of the somites to the vertebrae. Each somite induces a ventral root to grow out from the spinal cord. When the sclerotomes recombine, the cranial half of the first cervical sclerotome fuses with the occipital sclerotome above contributing to the occipital bone of the skull. The cervical nerves beginning with C1 exit above the corresponding vertebra. Nerve C8 exits below the seventh cervical vertebra (C7), and thereafter nerves arise below their numbered vertebrae.

(By permission from Larsen WJ 1997 Human Embryology, 2nd edn. Edinburgh: Churchill Livingstone.)

The basic pattern of a typical vertebra is initiated by this recombination of caudal and cranial sclerotome halves (Fig. 44.10), followed by differential growth and sculpturing of the sclerotomal mesenchyme which encases the notochord and neural tube. The centrum encloses the notochord and lies ventral to the neural tube. Condensation of the sclerotomal mesenchyme around the notochord and right and left neural processes can be seen in stage 15 human embryos. The neural processes curve to enclose the neural tube and extend to the dorsolateral angles of the centrum. The neural arch consists of paired bilateral pedicles (ventrolaterally) and laminae.
(dorsolaterally) which coalesce in the midline dorsal to the neural tube to form the spinous process. On each side three further processes project cranially, caudally and laterally from the junction of the pedicle and laminae. The cranial and caudal projections are the blastemal articular processes (zygapophyses) which become contiguous with reciprocal processes of adjacent vertebrae; their junctional zones mark the future zygapophysial or facet joints. The lateral projections are the true vertebral transverse processes. Bilateral costal processes (ribs) grow anterolaterally from the ventral part of the pedicles (i.e. near the centrum), from the neighbouring perichordal disc, and, at most thoracic levels, with acquisitions from the next adjacent caudal pedicles. The costal processes expand to meet the tips of the transverse processes. The definitive vertebral body is compound, and is formed from a median centrum (derived from the cells of the peri-notochordal sheath), and bilaterally from the expanded pedicle ends (derived from the migrating sclerotomal populations). These portions of the vertebral body fuse at the neurocentral synchondroses.

The segmental nature of the vertebrae is promoted by the notochord, which induces the ventral elements of the vertebrae and represses dorsal structures, e.g. the spinous processes. Excision of the notochord in early embryos results in fusion of the centra and formation of a cartilaginous plate ventral to the neural tube. Dorsal segmentation is influenced by the spinal ganglia: experimental removal of the ganglia results in fusion of the neural arches and the formation of a uniform cartilaginous plate dorsal to the neural tube.

**INTERVERTEBRAL DISCS**

Vertebral centra are derived from caudal and cranial sclerotomal halves. An intervertebral disc is formed from the free somitocele cells within the epithelial somite which migrate with the caudal sclerotomal cells. The sclerotomal mesenchyme which forms the centra of the vertebrae replaces the notochordal tissue which it surrounds. In contrast, the notochord expands between the developing vertebrae as localized aggregates of cells and matrix which form the nucleus pulposus of the intervertebral disc (Figs 44.8 and 44.11). The intermediate part of each perichordal disc, which forms the anulus fibrosus, surrounds the nucleus pulposus and differentiates into an external laminated fibrous zone and an internal cuff (which lies next to the nucleus

---

**Fig. 44.10** Contribution of two adjacent somites to one vertebra and rib. The intervertebral disc and the costal head are derived from somitocele cells from one somite which migrate with the caudal half of the sclerotome. The proximal rib is formed from caudal and cranial somite halves with no mixing of cells; in the distal rib there is more mixing of cranial and caudal cells as segmentation diminishes in the ventral body wall.

The inner zone contributes to the growth of the outer. Near the end of the second month of embryonic life it begins to merge with the notochordal tissue, and is ultimately converted into fibrocartilage. After the sixth month of fetal life, notochordal cells in the nucleus pulposus degenerate, and are replaced by cells from the internal zone of the anulus fibrosus. This degeneration continues until the second decade of life, by which time all the notochordal cells have disappeared. In the adult, notochordal vestiges are limited, at the most, to non-cellular matrix.

Fig. 44.11 A, B. Vertebral development through blastemal, cartilaginous and pre- and postnatal ossificatory stages. C. Derivation of principal morphological parts of adult vertebrae.

The original sclerotomes are coextensive with the individual metameric body segments: each sclerotomic fissure, perichordal disc, and maturing intervertebral disc lie opposite the centre of each fundamental body segment. It therefore follows that the discs correspond in level to (i.e. form the anterior boundary of) the intervertebral...
foramina and their associated mixed spinal nerves, ganglia, vessels and sheaths. Posteriorly, the foramina are bounded by the capsules of the synovial facet joints; the rims of the vertebral notches of adjacent vertebrae lie cranially and caudally. Thus all the structures listed (and other associated ones) are often designated segmental, whereas vertebral bodies are designated intersegmental because of their mode of development.

(For further discussion of resegmentation theories, the reader is directed to Müller & O'Rahilly 1986; Huang et al 2000; Stern & Vasiliauskas 2000.)
DEVELOPMENT OF VERTEBRAE

The initial movements of sclerotomal cells round the neural tube and the expression of type II collagen signals the blastemal stage of vertebral development (Fig. 44.11). Chondrification begins at stage 17, initiating the cartilaginous stage. Each centrum chondrifies from one cartilage anlage. Each half of a neural arch is chondrified from a centre, starting in its base and extending dorsally into the laminae and ventrally into the pedicles, to meet, expand and blend with the centrum. By stage 23 there are 33 or 34 cartilaginous vertebrae, but the spinous processes have not yet developed, so the overall appearance is of total spina bifida occulta. Fusion of the spines does not occur until the fourth month. The transverse and articular processes are chondrified in continuity with the neural arches. Intervening zones of mesenchyme which do not become cartilage mark the sites of the facet joints and the complex of costovertebral joints, within which synovial cavities later appear.

A typical vertebra is ossified from three primary centres, one in each half vertebral arch and one in the centrum (see Fig. 42.24). Centres in arches appear at the roots of the transverse processes, and ossification spreads backwards into laminae and spines, forwards into pedicles and posterolateral parts of the body, laterally into transverse processes and upwards and downwards into articular processes. Classically centres in vertebral arches are said to appear first in upper cervical vertebrae in the ninth to 10th week, and then in successively lower vertebrae, reaching lower lumbar levels in the 12th week. However, in a radiographic study of unsexed human fetuses (Bagnall et al 1977), a pattern was noted which differed from such a simple craniocaudal sequence. A regular cervical progression was not observed. Centres first appeared in the lower cervical/upper thoracic region, quickly followed by others in the upper cervical region. After a short interval a third group appeared in the lower thoracolumbar region and remaining centres then appeared, spreading regularly and rapidly in craniocaudal directions.

The major part of the body, the centrum, ossifies from a primary centre dorsal to the notochord. Centra are occasionally ossified from bilateral centres which may fail to unite. Suppression of one of these produces a cuneiform vertebra (hemivertebra), which is one cause of lateral spinal curvature (scoliosis). At birth and during early postnatal years the centrum is connected to each half neural arch by a synchondrosis or neurocentral joint. In thoracic vertebrae costal facets on the bodies are posterior to neurocentral joints.

During the first year the arches unite behind, first in the lumbar region and then throughout the thoracic and cervical regions. In upper typical cervical vertebrae, centra unite with arches about the third year, but in lower lumbar vertebrae, union is not complete until the sixth. The upper and lower surfaces of bodies and apices of transverse and spinous processes are cartilaginous
until puberty, at which time five secondary centres appear, one in the apex of each transverse and spinous process and two annular epiphyses (‘ring apophyses’) for the circumferential parts of the upper and lower surfaces of the body. Costal articular facets are extensions of these annular epiphyses. They fuse with the rest of the bone at about 25 years. There are two secondary centres in bifid cervical spinous processes. Exceptions to this pattern of ossification are described in the appropriate subsections in Chapter 42.

Vertebrae are specified as to region very early in development. If a group of thoracic somites is transplanted to the cervical region, ribs will still develop. It is the sclerotome which is restricted: the myotome will produce muscle characteristic of the new location.

Occipitocervical junction

In humans, the junction between the head and neck (termed occipitocervical, craniovertebral or spinomedullary) is placed at the boundary between the fourth and fifth somites (Müller & O'Rahilly 1994). In avian embryos, where all embryonic stages may be obtained experimentally, the occipitocervical boundary has been determined as the fifth to sixth somite boundary (Wilting et al 1995). The boundary can first be determined in the human at stage 12 by the observation of hypoglossal nerve rootlets (Fig. 44.12). At stages 14 and 15 the junction is seen between the hypoglossal rootlets and the 1st spinal ganglion.
Fig. 44.12 Reconstructions of the occipitocervical region of human embryos. A, Stage 12: occipital somites innervated by hypoglossal fibres (small yellow circles). Three cervical somites are shown. The crest-derived ganglia of cranial nerves V, VII, VIII, IX, and X are shown in green. Neural crest associated with the occipital somites is hypoglossal and perhaps accessory (also shown in green). B, Stage 14: the somites have transformed into sclerotomes and moved ventrally. The less dense cranial and dense caudal parts of the sclerotomes and occipital sclerotomes 1–4 are indicated. Hypoglossal fibres and cervical ventral rami migrate through the less dense parts of the sclerotomes. The occipital neural crest is now seen to be mostly accessory. The cervical crest is subdivided into spinal ganglia. A perinotochordal sheath can be seen extending rostrally to the termination of the notochord. C, Stage 15: the dense parts of sclerotomes 1–8 are shown. Intersegmental arteries are visible in the less dense areas of the sclerotomes, as are the spinal nerve fibres. In all diagrams the occipitocervical junction is indicated by the asterisks and line.

The first occipital somite disappears early and the caudal three fuse to form the basiocciput. Occipital sclerotomes 3 and 4 are the most distinct at stage 14, by which time the first three sclerotomes have fused. Vertebrae are formed from the fifth somite caudally: the first cervical vertebra is formed by the caudal half of occipital somite 4 and the cranial half of cervical somite 1 (Fig. 44.9). This shift of somite number and vertebral number accounts for the production of seven cervical vertebrae from eight cervical somites.

The segmental pattern present in the cervical somites can be seen rostrally in the developing skull base, where mesenchymal condensations equivalent to the centra of occipital somites 2, 3 and 4 are apparent. The hypoglossal rootlets pass through the less dense portion of occipital sclerotome 4, accompanied by the hypoglossal artery. Occipital sclerotome 4 forms an incomplete centrum axially and exoccipital elements laterally, which are regarded as corresponding to neural arches. They form the rim of the foramen magnum. The occipital condyles develop from the first cervical somite (as also happens in the chick).

In the occipitocervical junctional region the centra formed from sclerotomes 5, 6 and 7 have a different fate from those more caudally placed. The lateral portions of these sclerotomes generally develop similarly to those of lower ones. In a study of occipitocervical segmentation in human embryos, Müller & O'Rahilly designated the three complete rostral centra which develop in the atlanto-axial region X, Y and Z (Fig. 44.13; Müller & O'Rahilly 1986). They noted that the height of the XYZ complex is equal to that of three centra elsewhere. X is on the level of sclerotome 5, and Y and Z are in line with sclerotome 6 and with the less dense portion of sclerotome 7. During stage 17 a temporary intervertebral disc appears peripherally between Y and Z. It begins to disappear in stage 21, although remains may be found in the adult. No disc develops between X and Y.
The origin of the anterior arch of the atlas is unclear. It is evident at stages
The posterior arch of the atlas arises from the dense area of sclerotome 5 at the level of X. The posterior arch of the atlas arises from the dense area of sclerotome 6 and is at the level of Y and Z, particularly Z. XYZ correspond to the three parts of the median column of the axis, where X represents the tip of the dens, Y represents the base of the dens and Z represents the centrum of the axis. The latter differs from other cervical vertebrae in that it is thicker and square-shaped.

The development of the cervical spine, particularly the upper cervical vertebrae, is closely related to the development of the basiocciput and exocciput: anomalous development will affect both regions. Anomalies of the occiput are associated with decreased skull base height; the dens lies at or above the level of the foramen magnum; a distinctive margin of the foramen magnum lies above the bottom of the posterior fossa; and the posterior arch of the atlas is at the same level as the foramen magnum. The last three structural defects are collectively termed basilar invagination. Malfusions of the caudal portion of occipital sclerotome 4 and the cranial portion of cervical sclerotome 1 may produce defects of the occipital condyles. Disassociated occipital condyles are called a proatlas, because in lower vertebrates the cranial half of the first cervical sclerotome forms a separate bone between the occipital bone and the atlas.

Decreased skull base height and diminished volume in the posterior fossa are structural anomalies associated with the Arnold–Chiari malformation. Although this is considered clinically to be a neurological defect, in that the medulla oblongata, and sometimes the cerebellar tonsils, project through the foramen magnum, there is good evidence that the underlying cause is a series of abnormalities of the occipitocervical junction. When the volume of the brain in the posterior cranial fossa and the volume of the fossa (delineated by bone and the tentorium cerebelli) were compared in controls and Arnold–Chiari cases, no significant difference was found between brain volume in the two groups, though the basiocciput, exocciput and supraocciput were significantly smaller in affected individuals (Nishikawa et al 1997). In patients with the Arnold–Chiari malformation, proatlas remnants and atlas assimilation are found. The sagittal canal diameter of the foramen magnum is critical: patients become symptomatic when this is less than 19 mm (Menezes 1995). Secondary skull base and cervical spine deformations, e.g. foramen magnum and cervical canal enlargement, may develop in association with the Arnold–Chiari malformation.

Most defects of the atlas do not contribute to abnormal occipito-cervical anomalies and are not associated with basilar invagination.
Abnormalities of the axis are usually concerned with fusion of the dens with the centrum of the second cervical sclerotomes. Using the classification of the three complete centra which develop in the atlanto-axial region as X, Y and Z (Müller & O'Rahilly 1986), failure of fusion of X with the YZ complex produces an ossiculum terminale, a dissociated apical odontoid epiphysis. Failure of fusion of the XY complex with Z at the dentocentral synchondrosis, or maintenance of the transitory intervertebral disc at this point, produces an os odontoideum, thought to be induced by excessive movement at the time of ossification of the dens (Crockard & Stevens 1995). Hypoplasia and aplasia of the X and Y centra, and aplasia of the Z centrum, will all lead to reduced size of the dens. There are widely differing views about whether this will lead to atlanto-axial instability.

C3–7, third to seventh cervical vertebrae

In cervical vertebrae 3–7 (Fig. 44.11) the transverse process is dorsomedial to the foramen transversarium. The costal process, corresponding to the head, neck and tubercle of a rib, limits the foramen ventrolaterally and dorsolaterally. The distal parts of these cervical costal processes do not normally develop; they do so occasionally in the case of the seventh cervical vertebra, and may even develop costovertebral joints. These cervical ribs may reach the sternum.

The seventh cervical vertebra is transitional in shape between cervical and thoracic vertebrae. The laminae are longer than other cervical vertebrae in the neonate and lie almost perpendicular to the basal plane; the inferior articular facets are more upright, and resemble those of thoracic vertebrae; and, in the lateral view, the superior articular facets extend transversely to the top of the transverse processes.

Anomalies of the lower cervical vertebrae are generally caused by inappropriate cervical vertebral fusion: collectively this is termed Klippel–Feil syndrome. This term includes all congenital fusions of the cervical spine, from two segments to the entire cervical spine. Affected individuals have a low posterior hairline, short neck and limitations of head and neck movement. Scoliosis and/or kyphosis is common.

Thoracic vertebrae

At stage 23 the neural processes of thoracic vertebrae are short, slightly bifurcated and joined by collagenous fibres. The transverse process is prominent. The three facets for articulation with the ribs at the costovertebral and costotransverse joints are present. The thoracic neurocentral and posterior synchondroses are not fused in the neonate: the posterior synchondroses close within 2 to 3 months of postnatal development and the neurocentral synchondroses are open until 5 to 6 years of age.
In general, the thoracic spine develops ahead of the cervical and lumbar spine. However, towards the end of the second month, ossification begins in the cartilaginous vertebrae in a craniocaudal progression.

**Ribs**

Ribs usually develop in association with the thoracic vertebrae. Occasionally they can arise from the seventh cervical and first lumbar vertebrae.

The costal processes attain their maximum length as the ribs in the thoracic region. Each rib originates from lateral sclerotomal populations, and forms from the caudal half of one sclerotome and the cranial half of the next subjacent sclerotome (Fig. 44.10). The head of the rib develops from somiteocele cells from one somite, which migrate with the caudal half of the sclerotome. The proximal portion of the rib forms from both caudal and cranial sclerotomal halves; there is no mixing of cells from these origins. The distal portion of the rib forms from caudal and cranial sclerotomal halves; these cells mix as the rib extends into the ventral body wall and segmentation diminishes.

The ribs arise anterolaterally from the ventral part of the pedicles, and form bilateral costal processes which expand to meet the tips of the transverse processes. As they elongate laterally and ventrally they come to lie between the myotomic muscle plates. In the thorax (Fig. 44.11) the costal processes grow laterally to form a series of precartilaginous ribs. The transverse processes grow laterally behind the vertebral ends of the costal processes, at first connected by mesenchyme which later becomes differentiated into the ligaments and other tissues of the costotransverse joints. The capitular costovertebral joints are similarly formed from mesenchyme between the proximal end of the costal processes and the perichordal disc, and the adjacent parts of two (sometimes one) vertebral bodies, which are derived from the neural arch. Ribs 1–7 (vertebrosternal) curve round the body wall to reach the developing sternal plates. Ribs 8–10 (vertebrochondral) are progressively more oblique and shorter, only reaching the costal cartilage of the rib above, and contributing to the costal margin. Ribs 11 and 12 are free (floating), and have cone-shaped terminal cartilages to which muscles become attached (p. 921).

**Lumbar vertebrae**

The costal processes do not develop distally in lumbar vertebrae (Fig. 44.11). Their proximal parts become the ‘transverse processes', while the morphologically true transverse processes may be represented by the accessory processes of the vertebrae. Occasionally, movable ribs may develop in association with the first lumbar vertebra.
Lumbar intervertebral discs are thicker than thoracic discs. By stage 23 the anulus fibrosus can be seen in the peripheral part, and internally the notochordal cells are expanding to form the nucleus pulposus.

**Sacrum**

Sacral vertebrae have lower centra and are narrower overall from side to side than their thoracic and lumbar counterparts. Each sacral vertebra is composed of a centrum and bilateral neural processes. The contribution of the costal processes to sacral development was examined by O'Rahilly et al (1990). These authors divided the neurocentral junctional area into two parts, anterolateral or alar, and posterolateral. They found the alar element in sacral vertebra 1 to be novel, since it was absent in lumbar vertebra 5. There is support for this view if the course of the dorsal rami of the spinal nerves is used to distinguish the costal elements ventrally from the transverse elements dorsally. The alar elements of the sacral vertebrae are ventral to the sacral dorsal rami, and both costal and transverse portions are posterolateral. The alar element of S1 and S2 forms the auricular surface of the sacrum. At stage 23 the cartilaginous sacral vertebrae have joined and the outline of the future bone can be recognized. Individual pedicles and laminae are very small and can be detected in S3–5.

Ossification of the vertebral column proceeds in a craniocaudal direction. After 16 weeks it has progressed to L5. Ossification of each additional vertebra occurs over a period of 2–3 weeks; S2 is ossified by 22 weeks.

Very rarely significant malformation of the sacral or lumbosacral vertebrae may develop, often in association with a maternal history of diabetes. When there is sacral agenesis, motor paralysis is profound below the affected vertebral level, whereas the sensory disturbance does not relate to the vertebral level so clearly and sensation may be present down to the knees. Bladder involvement is a consistent feature.
SPINA BIFIDA

Spina bifida is the generic term for a range of discrete defects of neurulation and subsequent vertebral formation. The spectrum of neural tube and vertebral defects includes a range of open neural tube defects: craniorachischisis (non-fusion of the entire neural tube and no vertebral arch development); anencephaly (non-fusion of the rostral portion of the neural tube with no calvarial or occipital development); and myelocele (non-fusion of caudal portions of the neural tube and local failure of vertebral arch development) (see Fig. 24.8).

Spina bifida cystica occurs where the meninges have developed adjacent to or over the defective neural tissue. Local accumulation of CSF may push a defective neural plaque or spinal cord superficial to the level of the vertebrae forming a meningomyelocele. Alternatively, a meningeal sac may protrude in the midline if one or two spinous processes are absent; this condition is a meningocele. In both cases the meningeal sac may be covered with skin or skin may be contiguous with the edges of a neural plaque.

Prior to antenatal diagnosis of spina bifida by ultrasonography, most live births with spina bifida cystica had meningomyelocele. Meningomyelocele occurs in thoracolumbar, lumbar or lumbosacral regions. Sacral lesions are less common. The vertebral lesion usually extends cranially further than the neural lesion, showing deformities of the vertebral bodies and laminae. Vertebrae may be wedge-shaped or hemivertebrae and ribs may be fused or absent. Concomitant kyphosis at birth is associated with a worse prognosis. Prenatal diagnosis of meningomyelocele and termination of affected fetuses has led to a significant decrease in the incidence of live births with this condition.

Up to 10% of spina bifida cystica cases are meningocele. This lesion may occur in cervical and upper thoracic levels or in lower lumbar and sacral levels: the latter are most common. In its mildest form no neurological abnormality occurs with this condition.

Spina bifida occulta affects about 5% of the population. Affected individuals have bifid spinous processes often at the lumbosacral junction. A very small proportion of those with this condition have a naevus, dimple or tuft of hair over the lesion.

Tethering of the cord and diastematomyelia

The greatest change of vertebral length occurs within the last 6 months of intrauterine life. When there is any degree of spina bifida, the upward migration of the spinal cord which normally occurs within the vertebral canal during growth is limited, and the cord is said to be tethered. Neurological
deficits caused by this condition in neonates become apparent soon after birth, although some individuals show symptoms later in life, especially degrees of urinary dysfunction.

Very rarely, tethering symptoms may be associated with abnormal development of the vertebral centra, e.g. when a midline cartilaginous or osseous spicule or a fibrous septum projects into the vertebral canal. These obstacles may split the spinal cord or intraspinal nerve roots into two columns, a condition termed diastematomyelia. Usually patients with this condition have a cutaneous abnormality, such as a dimple, pigmented naevi or patch of hair, along their back at the level of the tethering.
DEVELOPMENT OF DERMOMYOTOMES

The dermomyotome, which forms from the dorsal half of the early somite, gives rise to all the skeletal muscle in the trunk and limbs and the intrinsic muscles of the tongue. Muscles in the head arise from the unsegmented paraxial mesenchyme rostral to the occipital somites. The dorsomedial lip (border) of the dermomyotome is an infolding of the epithelial plate of the somite and becomes a proliferative epithelial site from which mediolateral growth of the dermomyotome itself occurs. Three structures are required for myogenesis, the neural tube, the notochord/neural floor plate complex and the (early) dorsally placed ectoderm. There is a balance between levels of Shh from the notochord and Wnts from the dorsal neural tube and ectoderm which promotes myogenesis; high levels of either alone lead to sclerotomal or nonmyogenic dermomyotomal development (Scaal & Christ 2004). Myogenic determination factors, MyoD, myogenin, Myf 5 and herculin/MRF 4 can first be detected in the medial half of the somite as early as stage II, several hours prior to the onset of myotome formation.

The mode of formation of mononucleated, postmitotic, primitive myotubes from the dermomyotome has been elucidated in the chick but not yet confirmed in mammals (Gros, Scaal & Marcelle 2004). In this model all four borders of the dermomyotome give rise to myotomal cells which are produced in two phases: initially from the dorsomedial dermomyotomal lip by direct ingression and bidirectional extension; later, in a second phase, the caudal dermomyotomal border, followed in turn by the cranial dermomyotomal border and lastly the ventrolateral dermomyotomal lip, start to release myotomal precursor cells. Those myotomal cells arising from the dorsomedial dermomyotomal border contribute cells exclusively to the epaxial domain, those from the ventrolateral border contribute cells exclusively to the hypaxial domain, and the cells arising from the cranial and caudal borders move into both epaxial and hypaxial domains (Scaal & Christ 2004) (Fig. 44.7).

EPAXIAL MUSCLE: DORSAL TRUNK MUSCLES

Epaxial muscles arise from the dorsomedial lip of the dermomyotome. Myotome cells are all postmitotic embryonic myoblasts: later in development they fuse to form syncytia which produce the intrinsic muscles of the back. They bridge the early segmental borders, joining vertebrae together. The epaxial muscles are innervated by the dorsal ramus of each spinal nerve. At later stages satellite cells enter the myotome. The mechanism of development of endo-, peri- and epimysium in relation to the epaxial muscles has not been determined.
HYPAXIAL MUSCLE: VENTROLATERAL TRUNK MUSCLES

Two modes of production of hypaxial musculature are seen, related to axial level (Fig. 44.7). At cervical and trunk levels, myotubes are produced by the ventrolateral edge of the dermomyotome in a manner similar to the production of epaxial muscles. As development proceeds there is lateral growth of the dermomyotome so that the ventrolateral border extends ventrolaterally into the developing lateral and ventral body wall. The somite structures that invade the somatopleure of the abdominal and thoracic wall thus consist of two layers, dermomyotome and myotome, that give rise to the muscle blastemata for the intercostal and oblique muscles, transversus abdominis and rectus abdominis. At this time the number of somatopleural fibroblasts situated within the muscle-forming zone increases, and myotubes can be first seen. There is a subsequent ventral shift of the already separated muscle blastemata within the growing abdominal wall as they attain their definitive positions. Muscle differentiation continues and muscular connective tissue, tendons and aponeuroses develop.

At occipital and limb levels a ventrolateral dermomyotomal lip is not formed in the same way; cells undergo epithelial/mesenchymal transformation and migrate to their destination. Myoblasts move from the occipital dermomyotomes into the developing mandibular processes to form the intrinsic muscles of the tongue, whereas those opposite the early limb buds migrate into the limbs as dorsal and ventral muscle masses which give rise to the shoulder, hip and appendicular muscles. (For a review of dermomyotomal development see Scaal & Christ 2004.)
OTHER STRUCTURES DERIVED FROM THE SOMITES

Dermal precursors arise from the central portion of the dermomyotome and possibly also from the dorsomedial dermomyotome lip (Fig. 44.7). The cells undergo an epithelial/mesenchyme transformation from the dermomyotome and migrate to the dorsomedial subectodermal space overlying the dorsal neural tube. Their transformation seems to be controlled by factors from the neural tube. There is a sharp boundary between dermis which is somite-derived and that which is derived from the splanchopleuric mesenchyme of the lateral plate (and which covers the limbs, part of the lateral and all of the ventral body wall).

Smooth muscle cells within and around the developing somites and endothelial cell precursors are now considered to arise from somitic cells. All compartments of the epithelial somite, including the somitocele cells, give rise to angioblasts. The early ventral half of the somite gives rise to the endothelium of ventrolateral blood vessels. Angioblastic cells arising from the dorsomedial dermomyotome migrate mainly into the dorsal dermis, whereas those arising from the dorsolateral part move to the ventrolateral body wall and limbs (Scaal & Christ 2004).

Section 6 – PECTORAL GIRDLE AND UPPER LIMB

CHAPTER 45 – Pectoral girdle and upper limb: overview and surface anatomy

This chapter is divided into two sections. The first is an overview of the general organization of the upper limb, with particular emphasis on the distribution of the major blood vessels and lymphatic channels, and of the branches of the brachial plexus: it is intended to complement the detailed regional anatomy described in Chapters 46 to 50 Chapter 47 Chapter 48 Chapter 49 Chapter 50. The second section describes the surface anatomy of the upper limb.

BONES AND JOINTS

The bones of the upper limb are the clavicle, scapula, humerus, radius and ulna (connected for a large portion of their length by an interosseous membrane) and the bones of the hand, i.e. the carpals, metacarpals and phalanges (Figs 45.1, 45.2).
Fig. 45.1 Overview of the bones of the left pectoral girdle and upper limb: anterior view.
The shoulder girdle is extremely mobile because reciprocal movements at the sternoclavicular and glenohumeral joints enable 180° abduction of the upper limb. Movement occurs in all three planes at the glenohumeral joint.

The elbow joint is a hinge joint. It incorporates the superior (proximal) radio-ulnar joint within its capsule. The proximal and distal radio-ulnar joints permit
pronation and supination of the forearm – a unique feature of the primate upper limb.

The range of movement at the condyloid wrist joint, between the distal ends of the radius and ulna and the proximal carpal bones, is supplemented by gliding movements between the carpal bones. The saddle-shaped first carpometacarpal joint, between the trapezium and the base of the first metacarpal, is unique to the primate forelimb and permits opposition of the thumb. The hand is clenched by flexion at the metacarpophalangeal joints, supplemented by gliding movements of the fourth and fifth carpometacarpal joints. In grasping, the thumb is of equal value to the remaining four digits: loss of the thumb is almost as disabling as loss of all of the other digits.
SKIN, FASCIA AND SOFT TISSUES

The skin of the anterior aspect of the upper arm and forearm differs from that of the posterior aspect in that it is thinner and hairless. The palmar skin is thick and hairless: firm attachments to the underlying palmar fascia reflect its role in gripping and shock absorption. The dorsal skin of the hand is much thinner, lax and mobile, and this allows the extensor tendons to glide underneath the subcutaneous tissue.

The direction in which skin tension is greatest varies regionally in the upper limb as in other areas of the body. Skin tension lines that follow the furrows formed when the skin is relaxed are known as 'relaxed skin tension lines' and can act as a guide in planning elective incisions.

The superficial fascia is a layer of subcutaneous fatty tissue. Its thickness depends on the degree of obesity of the subject: measurement of the thickness of the subcutaneous tissue of the posterior upper arm is used as an indicator of obesity. With the exception of the digital pads, there is less subcutaneous tissue in the palm of the hand than on the dorsum of the hand.

The depth of deep fascia varies according to the stresses to which it is subjected in the different areas of the limb. In the upper arm it is a thin but quite obvious layer. Intermuscular septa pass to the medial and lateral sides of the humerus, separating the upper arm muscles into anterior and posterior groups within their respective compartments. Each muscle also lies within its own delicate fascial sheath arrangement that allows individual muscles to glide upon each other.

The deep fascia condenses anteriorly at the elbow as the tough bicipital aponeurosis; it is otherwise relatively thin in the forearm where it is attached along the subcutaneous border of the ulna. Intermuscular septa divide the forearm into three compartments, namely, anterior (contains the flexor group of muscles), posterior (extensors) and the mobile wad compartment for brachioradialis and extensor carpi radialis longus and brevis.

At the wrist the deep fascia becomes condensed anteriorly and posteriorly as the flexor and extensor retinacula respectively. Further condensation occurs in the palm of the hand, where the palmar aponeurosis is reinforced by the insertion of the tendon of palmaris longus, and in the flexor tendon sheaths and fascial system associated with the digits.
MUSCLES

Posterior and anterior muscle groups connect the pectoral girdle to the axial skeleton; the only bony connection is at the sternoclavicular joint. The posterior muscles are trapezius, levator scapulae and the rhomboid muscles: their actions include raising the shoulder and drawing the scapula medially. The anterior muscles are pectoralis minor, serratus anterior, and subclavius. Serratus anterior and trapezius together rotate the scapula in abduction of the arm.

Latissimus dorsi (posteriorly) and pectoralis major (anteriorly) run from the axial skeleton to the humerus. They are both powerful adductors and medial rotators of the shoulder; latissimus dorsi is also a powerful extensor.

A large group of muscles arise from the shoulder girdle and pass to the humerus. They are the four muscles of the rotator cuff (subscapularis, supraspinatus, infraspinatus and teres minor), teres major, deltoit, the clavicular origin of pectoralis major, biceps brachii, coracobrachialis and the long head of triceps.

The muscles of the upper arm can be divided into an anterior group of elbow flexors (biceps brachii, brachialis and coracobrachialis) and a posterior group of elbow extensors (triceps and anconeus). Biceps brachii is also a powerful supinator of the radio-ulnar joints.

The extensor muscles of the wrist and fingers, together with brachioradialis and a slip of origin of supinator, arise from the lateral epicondyle of the humerus. The principal head of pronator teres, the carpal flexor muscles, palmaris longus and, at a deeper level, the main origin of flexor digitorum superficialis, all arise from the medial epicondyle of the humerus. More deeply, flexor pollicis longus, flexor digitorum profundus and pronator quadratus arise from the anterior aspects of the shafts of the radius and ulna and the intervening interosseous membrane. Abductor pollicis longus, extensors pollicis longus and brevis and extensor indicis all arise from the posterior aspects of these bones and the intervening interosseous membrane.

The small, intrinsic, muscles of the hand consist of a thenar and a hypothenar group, and the muscles of the palm (the anterior and posterior interossei and the lumbricals). They are all concerned with the intricate movements of the digits.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIAL SUPPLY

The blood supply to the skin of the upper limb comes from a combination of direct cutaneous, fasciocutaneous and musculocutaneous vessels (Figs 45.3, 45.4; see Fig. 7.19).

Fig. 45.3 Overview of arteries of the left upper limb.
The axial artery to the upper limb is the subclavian artery, which becomes the axillary artery after crossing the lateral edge of the first rib. The axillary artery becomes the brachial artery as it crosses the distal edge of the posterior axillary fold, i.e. at the lower border of teres major. At first, the brachial artery lies in the flexor compartment on the medial side of the upper arm, but later it inclines laterally until it lies anterior to the elbow joint. Just distal to the elbow, it divides into the radial and ulnar arteries, both of which remain in, and supply, the flexor compartment. The ulnar artery almost immediately gives rise to the common interosseous artery, and this divides into anterior and posterior interosseous arteries which travel towards the wrist on either side of the interosseous membrane (the anterior interosseous artery lies directly on the membrane and the posterior interosseous artery is separated from it by the deep extensor muscles).

The muscles and other components of the extensor aspect are supplied by the profunda brachii artery in the upper arm, and by the posterior interosseous artery in the forearm. The hand is supplied by rich, and somewhat variable, anastomoses between branches of the radial and ulnar arteries, principally on its palmar aspect.

Each upper limb joint is supplied by an extensive anastomosis of arteries fed by descending vessels that arise proximal to the joint and ascending recurrent branches that arise distal to the joint.
VENOUS DRAINAGE

The venous drainage of the upper limb is composed of superficial and deep groups of vessels.

The superficial group starts as an irregular dorsal arch on the back of the hand. The cephalic vein begins at the radial extremity of the arch, ascends along the lateral aspect of the arm within the superficial fascia and then pierces the deep fascia to enter the axillary vein just distal to the clavicle (Fig. 45.5). The basilic vein drains the ulnar end of the arch, passes along the medial aspect of the forearm, pierces the deep fascia at the elbow and joins the venae comitantes of the brachial artery to form the axillary vein. In front of the elbow, the prominent median cubital vein links the cephalic and basilic veins. It receives a number of tributaries from the front of the forearm and gives off the deep median vein which pierces the fascial roof of the antecubital fossa to join the venae comitantes of the brachial artery.
The deep group of veins accompany the arteries, usually as venae comitantes, and ultimately become the axillary and then the subclavian vein. They drain the tissues beneath the deep fascia of the upper limb and are connected to the superficial system by perforating veins.
LYMPH NODES AND DRAINAGE

Superficial tissues

Superficial lymphatic vessels begin in cutaneous plexuses. In the hand, the palmar plexus is denser than the dorsal plexus. Digital plexuses drain along the digital borders to their webs, where they join the distal palmar vessels, which pass back to the dorsal aspect of the hand. The proximal palm drains towards the carpus, medially by vessels that run along its ulnar border, and laterally to join vessels draining the thumb. Several vessels from the central palmar plexus form a trunk that winds round the second metacarpal bone to join the dorsal vessels that drain the index finger and thumb.

In the forearm and arm, superficial vessels run with the superficial veins. Collecting vessels from the hand pass into the forearm on all carpal aspects. Dorsal vessels, after running proximally in parallel, curve successively round the borders of the limb to join the ventral vessels. Anterior carpal vessels run through the forearm parallel with the median vein of the forearm to the cubital region, then follow the medial border of biceps brachii before piercing the deep fascia at the anterior axillary fold to end in the lateral axillary lymph nodes (Fig. 45.6).
Lymph vessels that lie laterally in the forearm receive vessels that curve round the lateral border from the dorsal aspect of the limb. They follow the cephalic vein to the level of the deltoid tendon, where most incline medially to reach the lateral axillary nodes; a few continue with the vein and drain into the infraclavicular nodes. Vessels lying medially in the forearm are joined by vessels that curve round the medial border of the limb. They follow the basilic vein. Proximal to the elbow some end in supratrochlear lymph nodes whose efferents, together with the medial vessels that have bypassed them, pierce the deep fascia with the basilic vein and end in the lateral axillary nodes or deep lymphatic vessels.

Collecting vessels from the deltoid region pass round the anterior and posterior axillary folds to end in the axillary nodes. The scapular skin drains either to subscapular axillary nodes or by channels that follow the transverse cervical vessels to the inferior deep cervical nodes.

**Lymphatic drainage of deep tissues**

Deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) to the lateral axillary nodes. They are less numerous than the superficial vessels and communicate with them at intervals. A few lymph nodes occur along the vessels. Scapular muscles drain mainly to the subscapular axillary
nodes, and pectoral muscles drain mainly to the pectoral, central and apical nodes (Fig. 45.6).
INNERVATION

OVERVIEW OF THE BRACHIAL PLEXUS

The brachial plexus is formed by the union of the ventral rami of the lower four cervical nerves and the greater part of the first thoracic ventral ramus (Fig. 45.7; see Fig. 46.29).

![Diagram of the brachial plexus](image)

**Fig. 45.7** A schematic plan of the left brachial plexus.
*(Adapted from Drake, Vogl and Mitchell 2005.)*

The fourth ramus usually gives a branch to the fifth, and the first thoracic ramus frequently receives a branch from the second. These ventral rami are the roots of the plexus: they are almost equal in size but variable in their mode of junction. Contributions to the plexus by C4 and T2 vary. When the branch from C4 is large, that from T2 is frequently absent and the branch from T1 is reduced, forming a 'prefixed'
type of plexus. If the branch from C4 is small or absent, the contribution from C5 is reduced but that from T1 is larger and there is always a contribution from T2: this arrangement constitutes a 'postfixed' type of plexus.

Close to their exit from the intervertebral foramina, the fifth and sixth cervical ventral rami receive grey rami communicantes from the middle cervical sympathetic ganglion, and the seventh and eighth rami receive grey rami from the cervicothoracic ganglion. The first thoracic ventral ramus receives a grey ramus from, and contributes a white ramus to, the cervicothoracic ganglion.

The most common arrangement of the brachial plexus is as follows: the fifth and sixth rami unite at the lateral border of scalenus medius as the upper trunk; the eighth cervical and first thoracic rami join behind scalenus anterior as the lower trunk; the seventh cervical ramus becomes the middle trunk. The three trunks incline laterally, and either just above or behind the clavicle each bifurcates into anterior and posterior divisions. The anterior divisions of the upper and middle trunks form a lateral cord that lies lateral to the axillary artery. The anterior division of the lower trunk descends at first behind and then medial to the axillary artery and forms the medial cord; it often receives a branch from the seventh cervical ramus. Posterior divisions of all three trunks form the posterior cord, which is at first above, and then behind, the axillary artery. The posterior division of the lower trunk is much smaller than the others and is frequently derived from the eighth cervical ramus before the trunk is formed; it contains few, if any, fibres from the first thoracic ramus.

**Axillary nerve (C5, 6)**

The axillary nerve is a branch of the posterior cord of the brachial plexus. It winds posteriorly around the neck of the humerus together with the circumflex humeral vessels, and supplies deltoid and teres minor and an area of skin over the deltoid region (Fig. 45.8).
Radial nerve (C5–8, T1)

The radial nerve is the continuation of the posterior cord of the brachial plexus (Fig. 45.9). In the upper arm it lies in the spiral groove of the humerus where it is accompanied by the profunda brachii artery and its venal comitantes. It enters the posterior (extensor) compartment and supplies triceps, then re-enters the anterior compartment of the arm by piercing the lateral intermuscular septum. At the level of the lateral epicondyle it gives off the posterior interosseous nerve, which passes between the two heads of supinator and enters the extensor compartment of the forearm. The posterior interosseous nerve supplies these muscles, while the radial nerve proper continues into the forearm in the anterior compartment deep to brachioradialis and terminates by supplying the skin over the posterior aspect of the thumb, index, middle and radial half of the ring finger.
Musculocutaneous nerve (C5–7)

The musculocutaneous nerve is formed from the continuation of the lateral cord of the brachial plexus. It pierces and supplies coracobrachialis, biceps and brachialis, and then continues into the forearm as the lateral cutaneous nerve of the forearm (Fig. 45.10).
Median nerve (C6–8, T1)

The median nerve is formed by the union of the terminal branch of the lateral and medial cords of the brachial plexus (Fig. 45.11). It has no branches in the upper arm. It enters the forearm between the two heads of pronator teres and gives off the anterior interosseous nerve, which supplies all the flexor muscles of the forearm apart from flexor carpi ulnaris and the ulnar half of flexor digitorum profundus. The median nerve itself passes deep to the flexor retinaculum at the wrist. On entering the palm, it gives off motor branches to the thenar muscles and the radial two lumbricals, and cutaneous branches to the palmar aspect of the thumb, index and middle fingers and the radial half of the ring finger.
Fig. 45.11 Motor and sensory branches of the median nerve. Flexor pollicis brevis may be supplied by both median nerve and ulnar nerve.

Ulnar nerve (C7, C8, T1)

The ulnar nerve is the continuation of the medial cord of the brachial plexus (Fig. 45.12). Like the median nerve, it has no branches in the upper arm. It enters the posterior compartment of the upper arm midway down its length by piercing the medial intermuscular septum, passes behind the medial epicondyle of the humerus to enter the forearm and descends to the wrist deep to flexor carpi ulnaris. The ulnar nerve supplies flexor carpi ulnaris and the ulnar half of flexor digitorum profundus. Just proximal to the wrist it gives off a dorsal cutaneous branch that supplies the skin over the dorsal aspect of the little finger and the ulnar half of the ring finger, and then crosses into the palm superficial to the flexor retinaculum in Guyon's canal. It divides into a motor branch, which supplies the hypothenar muscles, the intrinsic muscles of
the hand (apart from the radial two lumbricals) and adductor pollicis, and cutaneous branches, which supply the skin of the palmar aspect of the little finger and the ulnar half of the ring finger.

Fig. 45.12 Motor and sensory branches of the ulnar nerve together with the medial cutaneous nerve of the arm and the forearm. Flexor pollicis brevis may be supplied by both median nerve and ulnar nerve.
AUTONOMIC INNERVATION

The autonomic supply to the limbs is exclusively sympathetic. The preganglionic sympathetic inflow to the upper limb is derived from neurones in the lateral horn of the upper thoracic spinal segments T2–6(7). Fibres pass in white rami communicantes to the thoracic sympathetic chain and synapse in the stellate and second thoracic ganglia. Postganglionic fibres to the skin are distributed via cutaneous branches of the brachial plexus. The blood vessels to the upper limb receive their sympathetic supply via adjacent peripheral nerves, thus the median nerve supplies postganglionic sympathetic fibres to the brachial artery and the palmar arches, and the ulnar nerve supplies the ulnar artery.
MOVEMENTS, MUSCLES AND SEGMENTAL INNERVATION

Most limb muscles are innervated by neurones derived from more than one segment of the spinal cord. The predominant segmental origin of the nerve supply for each of the muscles of the upper limb and for the movements which take place at the joints of the upper limb is summarized in Tables 45.1–45.4. Red has been used in Table 45.1 to highlight those muscles or movements which have diagnostic value (see below). The following caveats should be borne in mind when consulting these tables.

Table 45.1 -- Movements, muscles and segmental innervation in the upper limb. Muscles and movements that have diagnostic value are marked in red

Movements

At the central nervous level of control, muscles are not recognized as individual actuators but as components of movement, and may therefore contribute to several types of movement, acting variously as prime movers, antagonists, fixators or synergists. For example, serratus anterior acts as an antagonist of trapezius as the scapula moves around the thorax, whereas both muscles act together as prime movers during the forward rotation of the scapula. Some muscles have been included in more than one place in Table 45.1, on the basis that a muscle which acts across one joint can produce a combination of movements (e.g. flexion with medial rotation, or extension with adduction) and a muscle which crosses two joints can produce more than one movement. It must also be remembered that these listings are not exhaustive.

Nerve roots

There is no universal consensus concerning the contribution that individual spinal roots make to the innervation of individual muscles: the most positive identifications, which are limited, have been obtained by electrically stimulating spinal roots and recording the evoked electromyographic activity in the muscles. Much of the information in Tables 45.1–45.4 is therefore based on neurological experience gained in examining the effects of lesions, and some of it is far from new. In Table 45.1, spinal roots have been given the same colour (light peach, dark peach, red) when they innervate a muscle to a similar extent, or when differences in their contribution have not been described. Red has been used to indicate roots from which there is known to be a dominant contribution. From a clinical viewpoint, some of these roots may be regarded as innervating the muscle almost exclusively, e.g. deltoid by C5, brachioradialis by C6, and triceps by C7. Minor contributions have been retained in the table in order to increase its utility in other contexts, such as electromyography and comparative anatomy.

Neurological location of a lesion
In clinical practice it is only necessary to test a relatively small number of muscles in order to determine the location of a lesion. Any muscle to be tested must satisfy a number of criteria. It should be visible, so that wasting or fasciculation can be observed, and the muscle consistency with contraction can be felt. It should have an isolated action, so that its function can be tested separately. It should help to differentiate between lesions at different levels in the neuraxis and in the peripheral nerve, or between peripheral nerves. It should be tested in such a way that normal can be differentiated from abnormal, so that slight weakness can be detected early with reliability. Some preference should be given to muscles with an easily elicited reflex.

Table 45.4 gives a list of movements and muscles chosen according to these criteria. For example, with an upper motor neurone lesion, shoulder abduction, elbow extension, wrist and finger extension and finger abduction are weaker than their opposing movements. Since this weakness may be more distal than proximal or vice versa, normal shoulder abduction and finger abduction excludes an upper motor neurone weakness of the arm. Some muscles are difficult to test but are included for special reasons, e.g. the strength of brachioradialis is difficult to assess but it can be seen and felt, it is mostly innervated by the C6 root, and it has an easily elicited reflex.

Knowledge of the sequence in which motor branches leave a peripheral nerve to innervate specific muscles is very helpful in locating the level of a lesion. For example, with radial nerve lesions, if triceps is involved, then the lesion must be high in the axilla; if (as is usual), triceps is spared but brachioradialis, wrist extensors, finger extensors and the superficial radial nerve are all involved, then the lesion is in the arm, where the radial nerve is vulnerable to pressure against the humerus; if wrist extension is normal and the superficial radial nerve is not involved but finger extension is weak, then the lesion involves the posterior interosseous branch of the radial nerve.
SURFACE ANATOMY

SKIN

Palmar skin is marked by a number of creases, but they are of little value as points of reference. Transverse skin creases cross the palmar aspects of the fingers in three situations. The most proximal crease is placed at the junction of the digit with the palm and lies nearly 2 cm distal to the metacarpophalangeal joint, the intermediate crease lies opposite the proximal interphalangeal joint, and the distal crease is placed just proximal to the distal interphalangeal joint.

The flexor retinaculum may be outlined by defining its bony attachments. Its distal border, concave downwards, may be indicated on the surface by a curved line that joins the crest of the trapezium to the hook of the hamate. Its proximal border may be indicated by a curved line, concave upwards, that joins the tubercle of the scaphoid to the pisiform. Flexion of the wrist produces a number of transverse skin creases (usually two or three) at the wrist. The dominant crease, which is distal, overlies the proximal edge of the flexor retinaculum; the carpal tunnel lies distal to this crease, under the palmar skin.
SKELETAL LANDMARKS

The clavicle is both visible and palpable throughout its course. Its outline can be traced from the expanded sternal end, which forms the lateral boundary of the suprasternal notch, to the flattened acromial extremity. The line of the acromioclavicular joint is palpable as a distinct 'step' in an anteroposterior plane. The acromion can be traced from the acromioclavicular joint to its tip, and then backwards across the top of the shoulder until it meets the crest of the spine of the scapula at the prominent acromial angle. From this point, the spine of the scapula can be palpated as it passes medially from the acromial angle to the medial (vertebral) border of the scapula, where it lies opposite the spine of the third thoracic vertebra. The spine is subcutaneous and is easily visible in a thin subject.

The medial border of the scapula is hidden in its upper part by trapezius, but below the spine it can be palpated as it passes downwards to the inferior angle. Although covered by teres major and latissimus dorsi, the inferior angle can easily be felt when it is approached from below, and it can be seen to move laterally and forwards around the chest wall when the arm is raised above the head. The inferior angle of the scapula is at the level of the spine of the seventh thoracic vertebra and overlies the seventh rib. When a thoracotomy is being performed, it is a convenient landmark from which the ribs can be counted along the lateral chest wall.

A small depression can be seen inferior to the clavicle at the junction of its convex medial and concave lateral portions. This is the infraclavicular fossa (or deltopectoral triangle) and it intervenes between the surface elevations produced by the clavicular origins of pectoralis major and deltoid. The apex of the coracoid process lies 2.5 cm below the clavicle immediately to the lateral side of this fossa, under cover of the anterior fibres of deltoid. If the examining finger is passed laterally from the coracoid process, the lesser tubercle of the humerus will be felt below the tip of the acromion on deep pressure through deltoid. This bony prominence slips away from the examining finger when the humerus is rotated laterally or medially. The greater tubercle of the humerus is the most lateral bony point in the shoulder region and projects laterally below and in front of the acromial angle. It can also be felt to move on rotation of the humerus. When the arm is abducted, the head of the humerus can be palpated on deep pressure in the apex of the axilla.

The shaft of the humerus can only be felt indistinctly through its course because its outline is obscured by overlying muscles. Distally, the medial epicondyle of the humerus is a conspicuous landmark and is easily felt, particularly when the elbow is flexed; proximally it can be traced upwards into the medial supracondylar ridge. The ulnar nerve can be rolled from side to side posterior to the base of the medial epicondyle. The lateral epicondyle is
not so prominent, but its posterior surface is easily palpated and its lateral margin can be traced upwards into the lateral supracondylar ridge on deep pressure. Inspection of the posterior aspect of the extended elbow reveals a well-marked depression to the lateral side of the midline. This is bounded laterally by the fleshy elevation formed by the superficial group of forearm extensor muscles and medially by the lateral side of the olecranon. The floor of this depression contains, in its upper part, the posterior surface of the lateral epicondyle and, in its lower part, the head of the radius. Although the latter is covered by the anular ligament, it can be felt to rotate when the forearm is pronated and supinated. Between the lateral epicondyle and the radial head, the humero-radial part of the elbow joint can be felt as a distinct transverse depression.

When the elbow is extended, the apex of the olecranon can be felt and seen to lie in a line level with the two epicondyles. When the elbow is flexed, the apex of the olecranon descends and the three bony points then form the angles of a triangle. This relationship is lost in dislocation of the elbow. The posterior surface of the olecranon is subcutaneous and tapers from above downwards. It can be felt with ease immediately below the apex.

The level of the elbow joint is situated 2 cm below a line joining the two epicondyles. It slopes downwards and medially from its lateral extremity, and this obliquity produces the ‘carrying angle’. When the elbow is fully extended and the forearm and hand are in supination (‘the anatomical position’), the carrying angle is normally 165° in the female and 175° in the male. It disappears on full flexion of the elbow, when the shafts of the ulna and humerus come to lie in the same plane, and is also obscured in full pronation of the forearm.

The posterior border of the ulna is subcutaneous throughout its whole extent, from the subcutaneous surface of the olecranon superiorly to the styloid process below. Its position corresponds to the longitudinal furrow that can be seen on the posterior aspect of the forearm when the elbow is fully flexed, and which separates the flexor group of muscles from the extensors. In contrast, the shaft of the radius can only be felt indistinctly because it is covered by muscles. The rounded head of the ulna forms a surface elevation on the medial part of the posterior aspect of the wrist when the hand is pronated. The styloid process of the ulna projects distally from the posteromedial aspect of the head.

The expanded lower end of the radius forms a slight surface elevation on the lateral side of the wrist and can be traced downwards into the styloid process of the radius. The posterior aspect of the lower end of the radius is partly obscured by the extensor tendons but can be palpated without difficulty. It presents a tubercle (of Lister), which is grooved on its ulnar aspect by the tendon of extensor pollicis longus. The tubercle lies in line with the cleft
between the index and the middle fingers.

The wrist joint is easily identified between the carpus and the distal ends of the radius and ulna on flexion and extension of the wrist, even though it is covered by tendons. The line of the wrist joint corresponds to a line, convex upwards, that joins the styloid process of the radius to that of the ulna. It is delineated by the proximal of the two transverse anterior wrist skin creases.

Four of the bones of the carpus can be palpated and identified. The pisiform forms an elevation that can be both seen and felt on the palmar aspect of the wrist at the base of the hypothenar eminence. It can be moved over the articular surface of the triquetrum when the wrist is passively flexed. The hook of the hamate lies 2.5 cm distal to the pisiform and is in line with the ulnar border of the ring finger. It can be felt by deep pressure in this situation, and here the superficial division of the ulnar nerve can be rolled from side to side over the tip of the hook. The tubercle of the scaphoid is situated at the base of the thenar eminence, and in many subjects forms a small visible elevation. Immediately distal to it, but covered by the muscles of the thenar eminence, the crest of the trapezium can be identified on deep pressure. The scaphoid and trapezium can also be palpated in the ‘anatomical snuffbox’.

The heads of the metacarpal bones form the prominence of the knuckles, that of the middle finger being the most prominent. Their convex palmar aspects can be felt on deep pressure over the front of the metacarpophalangeal joints and can be gripped between the finger and the thumb. Deep pressure over the distal aspect of the head of the metacarpal bone reveals the base of the corresponding proximal phalanx; the line of the metacarpophalangeal joint can be detected on the dorsum of the hand as the fingers are flexed and extended. The dorsal aspects of the shafts of the metacarpal bones of the fingers and thumb and of the trapezium can be felt rather indistinctly, since they are obscured by the extensor tendons. The interphalangeal joints can be felt on the dorsal aspect of the flexed finger, just distal to the prominences caused by the heads of the proximal and middle phalanges.
MUSCULOTENDINOUS LANDMARKS

Deltoid may be delineated when the arm is abducted against resistance, and its tendon can be identified about half-way down the lateral aspect of the humerus. Its anterior border can be traced upwards and medially from the anterior aspect of the humerus, across the tendon of pectoralis major, to form the lateral boundary of the infraclavicular fossa. The posterior border runs upwards and medially from the posterior aspect of the deltoid tendon and reaches the crest of the spine of the scapula near its medial end. The normal rounded contour of the shoulder is produced by deltoid, which spreads out over the lateral aspect of the greater tubercle of the humerus. In dislocation of the shoulder, the greater tubercle is displaced medially, deltoid descends vertically to its humeral attachment, and the normal rounded contour of the shoulder is lost.

The rounded lower border of pectoralis major forms the anterior axillary fold. It is rendered more conspicuous when the abducted arm is adducted against resistance, e.g. when the hand is placed on the hip and pressed firmly against the trunk. When the arm is flexed to a right angle against resistance, the clavicular head of the muscle can be felt and seen to contract. When the flexed arm is extended against resistance, the clavicular head becomes relaxed but the sternocostal head stands out in relief.

The posterior fold of the axilla, produced by latissimus dorsi and the underlying teres major, reaches a lower level on the humerus than the anterior fold. Both latissimus dorsi and teres major participate in adduction of the arm: when the abducted arm is adducted against resistance, the posterior fold of the axilla is accentuated and the lateral border of latissimus dorsi can be traced downwards to its attachment to the iliac crest. When the arm is raised above the head, the lower five or six serrations of serratus anterior can be seen on the lateral aspect of the chest; they pass downwards and forwards to interdigitate with the serrations of external oblique. When serratus anterior is paralysed following injury to its nerve, the medial border, and especially the lower angle of the scapula, stand out prominently to produce a characteristic 'winged' appearance that can be accentuated by asking the patient to press both hands against a wall.

The belly of biceps brachii produces a conspicuous elevation on the anterior aspect of the arm. It diminishes above, where it is covered by pectoralis major, and below, where it is replaced by its tendon just above the elbow joint. Shallow furrows indicate its medial and lateral borders. When the elbow is flexed against resistance, biceps becomes still more obvious, and the bicipital tendon can be held between finger and thumb and traced down into the cubital fossa. With the arm held in this position, the sharp upper margin of the bicipital aponeurosis can be traced downwards and medially over the elevation produced by the superficial group of forearm flexor muscles.
Coracobrachialis emerges from the lateral wall of the axilla and forms a rounded ridge on the upper part of the medial side of biceps.

Posteriorly, the lateral head of triceps forms an elevation medial and parallel to the posterior border of deltoid and is thrown into prominence when the elbow is extended against resistance. On its medial side, the fleshy mass produced by the long head of triceps disappears above under cover of deltoid.

Brachioradialis is the most superficial of the muscles on the lateral side of the forearm. When the elbow is flexed in the semi-prone position against resistance, brachioradialis stands out as a prominent ridge extending upwards beyond the level of the elbow joint on the lateral side of the arm.

Proximal to the wrist crease, the prominent tendon of flexor carpi radialis can be seen and palpated when the wrist is flexed; the radial artery lies on its lateral side. By palpating lateral to flexor carpi radialis, 3 or 4 cm proximal to the wrist crease, it is possible to feel flexor pollicis longus (bending and straightening the thumb will confirm that the examining finger is in the correct place). The area on the ulnar side of flexor carpi radialis is packed most densely with functionally important structures. The median nerve lies very close to the skin surface and is therefore often injured in lacerations. It is covered by palmaris longus, when that muscle is present (best confirmed by pinching thumb and ring finger together, when the muscle will be seen to stand out). When palmaris longus is absent, only a thin covering of subcutaneous fat and deep fascia separates skin and nerve. The four tendons of flexor digitorum superficialis lie deep to the median nerve: the tendons for the middle and ring fingers lie in front of those for the index and little fingers as they pass deep to the flexor retinaculum and can be felt, and usually seen, to move on flexion of the fingers. Deeper still are the tendons of flexor digitorum profundus. The large and robust tendon of flexor carpi ulnaris is easily palpated on the ulnar side of the front of the wrist; the ulnar nerve, artery and venae comitantes lie in the shelter of its radial edge. Any sharp injury powerful enough to cut through this strong tendon usually has enough energy left to cut the nerve and vessel.

When the thumb is fully extended, a depression known as the anatomical snuffbox is seen on the lateral aspect of the wrist, immediately distal to the radial styloid process (Fig. 45.13). Palpating distally from the styloid process, three structures are usually encountered: the convex ovoid proximal articular surface of the scaphoid (best felt during alternate ulnar and radial deviation at the wrist); less distinctly, the radial aspect of the trapezium; and the expanded base of the first metacarpal (best felt during circumduction of the thumb). When clinically assessing wrist stability throughout the range of wrist movements, the scaphoid may be effectively compressed bidigitally, between index finger and thumb, along its oblique long axis between tubercle and
articular surface. The trapezium may be similarly compressed between its crest and radial aspect.

(C By permission from Lumley JSP 2002 Surface Anatomy, 3rd edn.)
The cephalic vein can be seen in the proximal roof of the snuffbox, and the pulsation of the radial artery can be felt in its depth. The snuffbox is bounded on the radial side by the tendons of abductor pollicis longus laterally and extensor pollicis brevis medially; these tendons lie close to each other. The tendon of extensor pollicis longus lies on the ulnar side of the snuffbox. It stands out conspicuously in full extension of the thumb, and can be seen to extend to the base of the distal phalanx of the thumb. If a finger is run along this tendon proximally, the superficial radial nerve can be rolled from side to side as it crosses the tendon.

The tendons of the radial extensors of the wrist can be identified on the back of the carpus when the fist is alternately clenched and relaxed. The tendons of extensor digitorum can readily be seen on the back of the hand when the fingers are fully extended. When the wrist is extended and deviated to the ulnar side, the tendon of extensor carpi ulnaris may be felt distal to the ulnar styloid as it crosses the wrist. The lateral part of the dorsal aspect of the hand between the index finger and thumb shows a fleshy elevation caused by the first dorsal interosseous: it becomes more conspicuous when the index finger is abducted against resistance. The corresponding anterior aspect of the first web space is formed by adductor pollicis.

The thenar eminence is a fleshy elevation produced by abductor and flexor pollicis brevis, which overlie opponens pollicis. On the medial side of the palm the hypothenar eminence is formed by the corresponding muscles of the little finger but is not so prominent. The medial border of the hand is formed by the medial aspect of the hypothenar eminence. The lateral border of the hand is formed by the dorsal aspect of the metacarpal bone of the thumb, which can be palpated throughout its extent.
VESSELS, PULSES AND NERVES

Arteries

By applying pressure laterally against the shaft of the humerus, the pulsation of the brachial artery can be felt in the furrow along the medial side of biceps and, more superiorly, in the depression posterior to coracobrachialis. In its lower part, the artery can be felt adjacent and posteromedial to the tendon of biceps before it disappears deep to the bicpital aponeurosis. Note that the brachial artery lies medial to the humerus in its upper part, but then lies directly in front of the distal end of the shaft of the bone. The proximity of the artery to a bone against which it can be compressed makes this the favoured site for non-invasive measurement of blood pressure. The median nerve is intimately related to the brachial artery throughout its course in the arm. It is at first lateral to the artery, then half-way along the arm the nerve crosses the artery, usually by passing in front of it, and descends on its medial side into the cubital fossa.

The ulnar artery begins in the midline of the forearm opposite the neck of the radius. In the upper, and deepest, part of its course through the forearm it can be represented by a line which passes downwards and medially across the elevation produced by the superficial flexor muscles of the forearm to reach the radial side of the ulnar nerve at the junction of the upper one-third with the lower two-thirds of the forearm. In the rest of its course, the ulnar artery lies along the radial side of the ulnar nerve.

The radial artery begins opposite the neck of the radius on the medial side of the tendon of biceps. It runs downwards and radially through the forearm to the wrist, where it crosses the anterior margin of the expanded lower end of the radius, passes posteriorly, deep to the tendons of abductor pollicis longus and extensor pollicis brevis, and enters the anatomical snuffbox where its pulsation can be felt. The upper part of its course can be represented by a line that passes deep to the medial part of the elevation produced by brachioradialis on the anterior aspect of the forearm.

The superficial palmar arch is indicated by a horizontal line that is usually 4 cm long at the level of the fully extended and partially abducted thumb. The deep palmar arch is indicated by a horizontal line 4 cm long from a point just distal to the hook of the hamate, and is about 1 cm proximal to the superficial arch.

Pulses, palpation and arterial gases

Brachial artery

The pulsation of the brachial artery can be felt in the furrow along the medial
side of biceps and, more superiorly, in the depression posterior to
coracobrachialis, by applying pressure laterally against the shaft of the
humerus. In its lower part, the artery can be felt adjacent and posteromedial
to the tendon of biceps before it disappears deep to the bicipital aponeurosis.
This is a useful site at which to pass an arterial catheter for coronary
angiography or cardiac catheterization.

Radial artery

The radial pulse is most easily felt on the ventral aspect of the wrist in the
interval between the tendon of flexor carpi radialis medially and the lower
lateral aspect of the radius. This is the most accessible pulse for palpation
under normal clinical circumstances.

Ulnar artery

The pulse of the ulnar artery is usually palpable on deep pressure radial to
the tendon of flexor carpi ulnaris at the wrist.

Sites for arterial cannulation

The most useful and commonly used site for cannulation of an artery (for
blood pressure monitoring and arterial blood sampling) in the upper limb is
the radial artery at the wrist. The presence of the palmar arches, which
supply a collateral circulation to the hand, means that thrombosis at this site
will not normally jeopardize the circulation of the hand.

The deep branch of the ulnar artery supplies the intrinsic muscles of the
thumb via the deep palmar anastomosis. Cannulation should therefore be
avoided if the ulnar artery has previously been damaged. An adequate
collateral circulation is demonstrated by Allen's test.

Allen's test

Allen's test examines the patency of the radial and ulnar arteries at the wrist
and so determines whether each individual artery is sufficient to maintain the
arterial supply to the hand in isolation. Both the radial and ulnar arteries are
compressed by the examiner's index and middle fingers of both hands. The
forearm is then elevated and the hand exsanguinated by clenching the fist.
The hand is then opened while continuing the arterial compression. The palm
of the hand appears pale unless there is an anomalous arterial supply, e.g.
from a persistent median artery. The brisk return of a normal pink colour to
the palmar skin following removal of digital pressure from one of the arteries
suggests that that artery is patent and capable of perfusing the hand
adequately in isolation. If the palmar skin remains pale, it must be assumed
that there is either a distal obstruction to the artery or that this artery cannot
adequately perfuse the hand in isolation. The test is then repeated with
Veins

At the wrist the cephalic vein is situated over the dorsolateral aspect of the lower end of the radius just proximal to the anatomical snuffbox. This is one of the few constantly sited peripheral veins. In the upper arm, the cephalic vein lies in the deltopectoral groove between deltoid and pectoralis major, and then ascends to the infraclavicular fossa, where it pierces the clavipectoral fascia to enter the axillary vein.

The median cubital and basilic veins may be identified in the cubital fossa. They are frequently covered by fat, especially in the female, which makes them difficult to see; however, they are usually palpable, especially if the venous return is occluded proximally by a tourniquet. The median cubital vein usually arises from the cephalic vein 2.5 cm distal to the lateral epicondyle of the humerus and runs upwards and medially to join the basilic vein 2.5 cm above the transverse crease of the elbow. The median vein of the forearm drains the venous plexuses on the palmar surface of the hand. It ascends on the front of the forearm and usually ends in either the basilic vein or the median cubital vein: sometimes it divides just distal to the elbow into two branches, one of which joins the basilic vein and the other the cephalic vein.

The bicipital aponeurosis is crossed by the median cubital vein, which runs medially and proximally from the cephalic vein to join the basilic vein. It may be distended into prominence by applying gentle constriction to the upper arm.

Venepuncture at the elbow

Blood sampling, blood transfusion and intravenous injection are commonly carried out near the elbow or more distally in the forearm: the largest vein is usually the median cubital. The cubital veins are also used for cardiac catheterization.

A high bifurcation of the brachial artery is seen occasionally and may produce an anomalous superficial ulnar artery that descends superficial to the common origin of the forearm flexor muscles. When this occurs, the ulnar artery, although deep to the deep fascia, may lie subcutaneously, either at the elbow or in the upper forearm. It is this anomalous ulnar artery, superficial to the bicipital aponeurosis and immediately deep to the median cubital vein, that is at greatest risk of intra-arterial puncture when the median cubital vein is selected for intravenous injection.

The cephalic vein may be accessed where it lies superficial to the distal end of the radius in the anatomical snuffbox. This site has many advantages for
placing an indwelling cannula when a lengthy period is contemplated: the position of the arm, forearm and hand are all optimal for this purpose.

**Lymph nodes**

Outlying supratrochlear nodes (in reality supra-epicondylar nodes) lie next to the basilic vein. If enlarged, they may be palpated along the line of the vein a few centimetres above the elbow joint.

**Nerves**

The trunks of the brachial plexus lie in the posterior triangle of the neck in the angle between the clavicle and lower posterior border of sternocleidomastoid, where they are palpable through the skin, platysma and deep fascia.

The initial course of the radial nerve may be indicated on the posterior aspect of the arm. It passes laterally from the start of the brachial artery to the junction of the upper and middle thirds of a line between the lateral epicondyle and deltoid tuberosity, and then continues anteriorly as far as the lateral epicondyle, a finger's breadth to the lateral side of the tendon of biceps. From here its course in the forearm can be mapped out along a line descending vertically to a point on the dorsum of the wrist midway between the head of the ulna and the dorsal tubercle of the radius. The point at which the posterior interosseous nerve winds round the upper end of the radius may be indicated by placing the index finger of the contralateral hand on the dorsal aspect of the head of the radius, and aligning the middle and ring fingers below the index finger. The ring finger then lies over the posterior interosseous nerve. This is an important surgical landmark in making an incision for exposure and removal of a fractured head of radius: the incision should not extend more than a finger's breadth below the head of the radius. The terminal branches of the superficial radial nerve can be palpated in the region of the anatomical snuffbox as they pass over the tendon of extensor pollicis longus.

The median nerve is intimately related to the brachial artery throughout its course in the upper arm. Its course can be marked on the surface by a line from the medial side of the brachial artery in the cubital fossa along the midline of the forearm to the wrist.

The ulnar nerve can be palpated and rolled by the examining fingers as it passes posterior to the medial epicondyle of the humerus. In the forearm its course corresponds to a line drawn from the base of the posterior aspect of the medial epicondyle of the humerus to the radial side of the pisiform and across the hook of the hamate. Deep pressure at these bony landmarks will produce paraesthesia. In the lower part of the forearm the line of the nerve lies along the radial side of the tendon of flexor carpi ulnaris medial to the
Dermatomes

Our knowledge of the extent of individual dermatomes, especially in the limbs, is largely based on clinical evidence. The dermatomes of the upper limb arise from spinal nerves C5–8 and T1: C7 supplies the central part of the hand (Figs 45.14, 45.15). Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

ulnar artery and its venae comitantes.
Fig. 45.14 The dermatomes of the left upper limb. Overlap across the axial lines is minimal, whereas overlap is considerable across the interrupted lines. A, Viewed from the anterior aspect. B, Viewed from the posterior aspect.

(Adapted from Drake, Vogl and Mitchell 2005.)

Fig. 45.15 The distribution of skin territories supplied by the cutaneous nerves of the left upper limb. A, Viewed from the anterior aspect. B, Viewed from the posterior aspect.
Myotomes

The predominant segmental origin of the nerve supply for each of the muscles of the upper limb and for the movements which take place at the joints of the upper limb are summarized in Tables 48.1–48.4.

Reflexes

Biceps jerk (C5, 6)

The elbow is flexed to a right angle and slightly pronated. A finger is placed on the biceps tendon and struck with a percussion hammer: this should elicit flexion and slight supination of the forearm.

Triceps jerk (C6–8)

The arm is supported at the wrist and flexed to a right angle. Triceps is struck with a percussion hammer just proximal to the olecranon: this should elicit extension of the elbow.

Radial jerk (C7, 8)

The radial jerk is a periosteal, not a tendon, reflex. The elbow is flexed to a right angle and the forearm placed in the mid position. The radial styloid is struck with the percussion hammer. This elicits contraction of brachioradialis, which causes flexion of the elbow.

Nerve blocks

Brachial plexus

There are three common approaches to achieve anaesthetic blockade of the brachial plexus: the interscalene, supraclavicular and axillary routes.

The interscalene route requires identification of the interscalene groove. The patient is asked to sniff, an action that involves the scalene muscles as accessory muscles of respiration. A needle is inserted perpendicular to the skin and enters the interscalene groove. Paraesthesia may be elicited, and local anaesthetic solution is injected. There is a risk that some local anaesthetic may move in a retrograde direction and reach the cervical epidural space. The proximal nature of the block means that there is almost always some involvement of the phrenic nerve, and sympathetic block (as evidenced by a Horner's syndrome) is universal.

The supraclavicular route places local anaesthetic solution in the plane occupied by the trunks of the brachial plexus as they emerge between scalenus anterior and medius on the first rib, immediately posterior to the third part of the subclavian artery. The site of injection is 2 cm above the
midpoint of the clavicle. The needle is directed backwards, inwards and downwards to make contact with the upper surface of the first rib. During this procedure the patient will usually complain of paraesthesia down the arm, which indicates that the needle is correctly placed. Preliminary aspiration ensures that a major vessel has not been punctured. If the first rib is missed, there is the risk of producing a pneumothorax. There is often a transient Horner's syndrome, caused by diffusion of the local anaesthetic towards the stellate ganglion.

The axillary approach blocks the nerves as they group around the axillary artery.

Wrist

Useful anaesthesia of the palm of the hand (except for the lateral surface of the thumb base) can be achieved by blockade of the ulnar and median nerves at the wrist. The ulnar nerve may be blocked via a needle inserted lateral to the tendon of flexor carpi ulnaris at the wrist. The median nerve may be blocked via a needle inserted at the midline between the tendons of palmaris longus and flexor carpi radialis at the level of the proximal wrist crease.

The radial nerve, which supplies the dorsal skin of the hand, may be blocked by injecting local anaesthetic around the subcutaneous dorsoradial border of the wrist, where branches of the nerve can be rolled over the tendon of extensor pollicis longus.

Digital nerve

The digital nerves lie on either side of the flexor sheath in a plane immediately anterior to the phalanx. Therefore the needle should be inserted on either side of the base of the digit, just anterior to the anterolateral margin of the phalanx. A common alternative approach to blocking the digital nerves is via a dorsal skin approach: the needle is inserted through the dorsal skin on either side of the base of the proximal phalanx and advanced towards the volar location of the digital nerves while continually infusing the local anaesthetic agent. This is thought to be less painful than the volar approach because the dorsal skin is less sensitive than the volar skin.
CHAPTER 46 – Pectoral girdle, shoulder region and axilla

SKIN AND SOFT TISSUE

SKIN

Cutaneous vascular supply

The area over the lateral end of the clavicle is supplied by the supraclavicular artery which pierces the deep fascia superior to the clavicle and anterior to trapezius (Fig. 45.4). In the majority of cases this artery arises from the superficial cervical/transverse cervical artery, but it occasionally arises from the suprascapular artery. The area over the deltoid is supplied by the anterior and posterior circumflex humeral arteries. The deltoid branch of the thoraco-acromial axis contributes to the blood supply of the anterior aspect of the shoulder via musculocutaneous perforators through deltoid. For details of the cutaneous supply to the anterior, lateral and posterior chest wall see page 915.

Cutaneous innervation

The segmental supply is described in Chapter 45, page 789. The cutaneous supply to the shoulder region comes from the supraclavicular nerves (p. 436, Fig. 45.15). The floor of the axilla together with part of the upper medial aspect of the arm is supplied by the intercostobrachial nerve (lateral branch of the second intercostal nerve). Occasionally the lateral branch of the third intercostal nerve contributes to the supply of skin in the floor of the axilla. The upper lateral cutaneous nerve of the arm supplies the skin over the inferolateral part of the shoulder.
SOFT TISSUE

Deep fascia

Fascia over deltoid

The deep fascia over deltoid sends numerous septa between its fasciculi and is continuous with the pectoral fascia in front and the thick and strong infraspinous fascia behind. Above it is attached to the clavicle, acromion and crest of the scapular spine; below it is continuous with the brachial fascia.

Subscapular fascia

The subscapular fascia is a thin aponeurosis attached to the entire circumference of the subscapular fossa; subscapularis itself is partly attached to its deep surface.

Supraspinous fascia

The supraspinous fascia completes the osseofibrous compartment in which supraspinatus is attached. It is thick medially, but thinner laterally under the coraco-acromial ligament. It is attached to the scapula around the boundaries of the attachment of supraspinatus.

Infraspinous fascia

The infraspinous fascia covers infraspinatus and is attached to the margins of the infraspinous fossa. The fascia is continuous with the deltoid fascia along the overlapping posterior border of deltoid.

Pectoral and axillary fascia

The pectoral fascia is a thin lamina which covers pectoralis major and extends between its fasciculi. It is attached medially to the sternum, above to the clavicle and is continuous inferolaterally with the fascia of the shoulder, axilla and thorax. Although thin over pectoralis major, it is thicker between this muscle and latissimus dorsi, and forms the floor of the axilla as the axillary fascia. The latter divides at the lateral margin of latissimus dorsi into two layers, which ensheathe the muscle and are attached behind to the spines of the thoracic vertebrae. As the fascia leaves the lower edge of pectoralis major to cross the axilla, a layer ascends under cover of the muscle and splits to envelop pectoralis minor: it becomes the clavipectoral fascia at the upper edge of pectoralis minor. The hollow of the armpit is produced mainly by the action of this fascia in tethering the skin to the floor of the axilla, and it is sometimes referred to as the suspensory ligament of the axilla. The axillary fascia is pierced by the tail of the breast (Ch. 54).
Clavipectoral fascia

The clavipectoral fascia is a strong fibrous sheet behind the clavicular part of pectoralis major. It fills the gap between pectoralis minor and subclavius, and covers the axillary vessels and nerves. It splits around subclavius and is attached to the clavicle both anterior and posterior to the groove for subclavius. The posterior layer fuses with the deep cervical fascia which connects omohyoid to the clavicle and with the sheath of the axillary vessels. Medially it blends with the fascia over the first two intercostal spaces and is attached to the first rib, medial to subclavius. Laterally, it is thick and dense, and is attached to the coracoid process, blending with the coracoclavicular ligament. Between the first rib and coracoid process the fascia often thickens to form a band, the costocoracoid ligament. Below this the fascia becomes thin, splits around pectoralis minor and descends to blend with the axillary fascia and laterally with the fascia over the short head of biceps. The cephalic vein, thoraco-acromial artery and vein, and lateral pectoral nerve pass through the fascia.

Spread of infection

When axillary suppuration occurs the local fascial arrangement affects the spread of pus. Suppuration may be superficial or deep to the clavipectoral fascia, either between the pectoral muscles or behind pectoralis minor. In the former, an abscess would appear at the edge of the anterior axillary fold or the groove between deltoid and pectoralis major; in the latter, pus would tend to surround vessels and nerves and ascend into the neck, the direction of least resistance. Pus may also track along vessels into the arm. When an axillary abscess is incised, the knife should enter the axillary ‘base’, midway between the anterior and posterior margins and near the thoracic side to avoid the lateral thoracic, subscapular and axillary vessels on the anterior, posterior and lateral walls respectively.
BONE

CLAVICLE

The clavicle lies almost horizontally at the root of the neck and is subcutaneous throughout its whole extent (Fig. 46.1). It acts as a prop which braces back the shoulder and enables the limb to swing clear of the trunk and transmits part of the weight of the limb to the axial skeleton. The lateral or acromial end of the bone is flattened and articulates with the medial side of the acromion, whereas the medial or sternal end is enlarged and articulates with the clavicular notch of the manubrium sterni and first costal cartilage. The shaft is gently curved and in shape resembles the italic letter f, being convex forwards in its medial two-thirds and concave forwards in its lateral third. The inferior aspect of the intermediate third is grooved in its long axis. The clavicle is trabecular internally, with a shell of much thicker compact bone in its shaft. Although elongated, the clavicle is unlike typical long bones in that it usually has no medullary cavity.
The female clavicle is shorter, thinner, less curved and smoother, and its acromial end is carried lower than the sternal in comparison with the male. In males the acromial end is on a level with, or slightly higher than, the sternal end when the arm is pendent. Midshaft circumference is the most reliable single indicator of sex: a combination of this measurement with weight and length yields better results. The clavicle is thicker and more curved in manual workers, and its ridges for muscular attachment are better marked.

**Lateral third**

The lateral third of the clavicle is flattened and has a superior and an inferior surface, limited by an anterior and a posterior border. The anterior border is concave, thin and roughened and may be marked by a small deltoid tubercle.

The posterior border, also roughened by muscular attachments, is convex backwards. The superior surface is roughened near its margins but is smooth centrally, where it can be felt through the skin. The inferior surface presents two obvious markings. Close to the posterior border, at the junction of the lateral fourth with the rest of the bone, there is a prominent conoid tubercle which gives attachment to the conoid part of the coracoclavicular ligament. A narrow, roughened strip, the trapezoid line, runs forwards and laterally from the lateral side of this tubercle, almost as far as the acromial end (Fig. 46.1B). The trapezoid part of the coracoclavicular ligament is attached to it. A small oval articular facet, for articulation with the medial aspect of the acromion, faces laterally and slightly downwards at the lateral end of the shaft.

Subclavius lies in a groove on the inferior surface (Fig. 46.1B). The clavipectoral fascia is attached to the edges of the groove; the posterior edge of the groove runs to the conoid tubercle, where fascia and conoid ligament merge. Lateral to the groove there is a laterally inclined nutrient foramen. Deltoid (anterior) and trapezius (posterior) are attached to the lateral third of the shaft: both muscles reach the superior surface. The coracoclavicular ligament, which is attached to the conoid tubercle and trapezoid line (Fig. 46.1B), transmits the weight of the upper limb to the clavicle, counteracted by trapezius which supports its lateral part. From the conoid tubercle this weight is transmitted through the medial two-thirds of the shaft to the axial skeleton.

The clavicle is often fractured, commonly by indirect forces, as a result of a violent impact to the hand or shoulder. The break is usually at the junction of the lateral and intermediate thirds, where the curvature changes, for this is the weakest part of the bone. A fracture medial to the conoid tubercle interrupts weight transmission from the arm to the axial skeleton. The resulting deformity is caused by the weight of the arm, which acts on the lateral fragment through the coracoclavicular ligament and draws it downwards. The medial fragment, as a rule, is a little displaced.

**Medial two-thirds**
The medial two-thirds of the shaft of the clavicle is cylindrical or prismoid in form and possesses four surfaces, but the inferior surface is often reduced to a mere ridge. The anterior surface is roughened over most of its extent but it is smooth and rounded at its lateral end, where it forms the upper boundary of the infraclavicular fossa. The upper surface is roughened in its medial part and smooth at its lateral end. The posterior surface is smooth and featureless. The inferior surface is marked, near the sternal end, by a roughened oval impression, which is often depressed below the surface. Its margins give attachment to the costoclavicular ligament, which connects the clavicle to the upper surface of the first rib and its cartilage. Rarely, this area is smooth or raised to form an eminence which may articulate with the upper surface of the first rib by means of a synovial joint. There is a groove in the long axis of the bone in the lateral half of the posterior surface.

The medial two-thirds provide attachment, anteriorly, for the clavicular head of pectoralis major: the area is usually clearly indicated on the bone. The clavicular head of sternocleidomastoid is attached to the medial half of the superior surface, but the marking on the bone is not very conspicuous. The smooth, posterior surface is devoid of muscular attachments except at its lower part immediately adjoining the sternal end, where the lateral fibres of sternohyoid are attached. Medially, this surface is related to the lower end of the internal jugular vein (from which it is separated by sternohyoid), the termination of the subclavian vein, and the start of the brachiocephalic vein. More laterally, it arches in front of the trunks of the brachial plexus and the third part of the subclavian artery. The suprascapular vessels are related to the upper part of this surface. The inferior surface gives insertion to subclavius in the subclavian groove: the clavipectoral fascia, which encloses subclavius, is attached to the edges of the groove. The posterior lip of the groove runs into the conoid tubercle and carries the fascia into continuity with the conoid ligament. A nutrient foramen is found in the lateral end of the groove, running in a lateral direction: the nutrient artery is derived from the suprascapular artery. The impression for the costoclavicular ligament is very variable in its character.

Sternal end

The sternal end of the clavicle is directed medially, and a little downwards and forwards, to articulate with the clavicular notch of the manubrium sterni. The sternal surface, usually irregular and pitted, is quadrangular (sometimes triangular). Its uppermost part is slightly roughened for attachment of the interclavicular ligament, sternoclavicular capsule and articular disc. Elsewhere the surface is smooth and articular and it extends onto the inferior surface for a short distance, where it articulates with the first costal cartilage. The sternal end of the clavicle projects upwards beyond the manubrium sterni and can be felt without difficulty and usually seen (a prominent clinical landmark), in the lateral wall of the jugular fossa.

Ossification

The clavicle begins to ossify before any other bone in the body, and is ossified from three centres. The shaft of the bone is ossified in condensed mesenchyme from two primary centres, medial and lateral, which appear between the fifth and sixth weeks of intrauterine life, and fuse about the 45th day. Cartilage then develops at both ends of the clavicle. The medial cartilaginous mass contributes more to growth in length than does the lateral mass: the two centres of ossification meet between the middle and
lateral thirds of the clavicle. A secondary centre for the sternal end appears in late teens, or even early twenties, usually 2 years earlier in females (Fig. 46.2). Fusion is probably rapid but reliable data are lacking. An acromial secondary centre sometimes develops at around 18 to 20 years, but this epiphysis is always small and rudimentary and rapidly joins the shaft.

![Fig. 46.2 The three constant centres of ossification of the clavicle.](image1)

The clavicle does not ossify exclusively by intramembranous ossification. In 14 mm embryos the clavicle is a band of condensed mesenchyme between the acromion and apex of the first rib, which is continuous with the sternal rudiment. Medial and lateral zones of early cartilage transformation (‘precartilage’) occur within this band, and intramembranous centres of ossification appear, and soon fuse, in the mesenchyme between them. Sternal and acromial zones soon become true cartilage into which ossification extends from the shaft. Length increases by interstitial growth of these terminal cartilages; the latter develop zones of hypertrophy, calcification and advancing endochondral ossification like other growth cartilages. Diameter increases by subperichondral deposition in the extremities and subperiosteal deposition in the shaft. Epiphyses are endochondral and probably fuse in the same way as they do in long bones. Defects of ossification in the clavicle and those cranial bones which ossify by intramembranous ossification occasionally coincide, e.g. in cleidocranial dysostosis.
SCAPULA

The scapula is a large, flat, triangular bone which lies on the posterolateral aspect of the chest wall, covering parts of the second to seventh ribs (Fig. 46.3, Fig. 46.4). It has costal and dorsal surfaces, superior, lateral and medial borders, inferior, superior and lateral angles, and three processes, the spine, its continuation the acromion and the coracoid process. The lateral angle is truncated and bears the glenoid cavity for articulation with the head of the humerus. This part of the bone may be regarded as the head, and it is connected to the plate-like body by an inconspicuous neck. The long axis of the scapula is nearly vertical and the relatively featureless costal surface can easily be distinguished from the dorsal surface, which is interrupted by the shelf-like projection of the spine (Fig. 46.3A). The bone is very much thickened in the immediate neighbourhood of the lateral border, which runs from the inferior angle below, to the glenoid cavity above. The main processes, and thicker parts of the scapula, contain trabecular bone; the rest consists of a thin layer of compact bone. The central supraspinous fossa and the greater part of the infraspinous fossa are thin and even translucent; occasionally the bone in them is deficient, and the gaps are filled by fibrous tissue.
The inferior angle lies over the seventh rib, or over the seventh intercostal space. It can be felt through the skin and the muscles which cover it and, when the arm is raised above the head, it can be seen to pass forwards round the chest wall. The superior angle is placed at the junction of the superior and medial borders, and is obscured by the muscles which cover it. The lateral angle is truncated and broadened. It constitutes the head of the bone. On its free surface it bears the glenoid cavity for articulation with the head of the humerus in the shoulder joint. Very gently hollowed out, the glenoid forms a poor socket for the humeral head. It is narrow above and wider below, and is pear-shaped in outline. Immediately above the glenoid cavity a small, roughened area encroaches on the root of the coracoid process and is termed the supraglenoid tubercle. The neck of the scapula is the constriction immediately adjoining the head. It can be identified most easily on its inferior and dorsal aspects. Ventrally, it can be regarded as extending between the infraglenoid tubercle and the anterior margin of the suprascapular notch.

**Costal surface**

The costal surface, which is directed medially and forwards when the arm is by the side, is slightly hollowed out, especially in its upper part (Fig. 46.3B).

Near the lateral border there is a longitudinal rounded ridge, prominent near the neck, but less so below, which is separated from the lateral border by a narrow grooved
Subscapularis arises from nearly the whole of the costal surface, including the grooved area immediately adjoining the lateral border, but excluding the area next to the neck of the bone. Small intramuscular tendons are attached to the roughened ridges which subdivide this surface incompletely into a number of smooth areas. The anterior aspect of the neck is separated from subscapularis by a bursal protrusion of the synovial membrane of the shoulder joint (subscapular ‘bursa’). The lower five or six digitations of serratus anterior are attached to an oval area near the inferior angle. The remainder of the muscle is inserted into a narrow strip along the ventral aspect of the medial border, which is wider above, where it receives the large first digitation. The longitudinal thickening of the bone near the lateral border provides a lever of the necessary strength to withstand the pull of serratus anterior on the inferior angle during lateral scapular rotation, when the glenoid cavity is turned to face more directly upwards as the arm is raised from the side and carried above the head against gravity.

Dorsal surface

The dorsal surface is divided by the shelf-like spine of the scapula into a small upper and a large lower area, which are confluent at the spinoglenoid notch between the lateral border of the spine and the dorsal aspect of the neck (Fig. 46.3A).

Supraspinatus is attached to the medial two-thirds of the supraspinous fossa on the dorsal surface: the fascia which covers the muscle is attached to the margins of the fossa. Teres minor is attached to the upper two-thirds of a flattened strip which adjoins the lateral border. The strip is grooved near its upper end by the circumflex scapular vessels, which pass between teres minor and the bone as they enter the infraspinous fossa. The lower limit of the attachment of teres minor is indicated by an oblique ridge, which runs from the lateral border to the neighbourhood of the inferior angle and cuts off a somewhat oval area where teres major is attached. The dorsal aspect of the inferior angle may give origin to a small slip which joins the deep surface of latissimus dorsi. The infraspinous fossa is hollowed out laterally but is convex medially. Infraspinatus is attached to the infraspinous fossa, with the exception of an area near the neck of the bone. The strong infraspinatus fascia passes onto teres minor and teres major, and sends fascial partitions between them which reach the bone along the ridges which mark the limits of their attachments.

Superior border

The superior border, thin and sharp, is the shortest. At its anterolateral end it is separated from the root of the coracoid process by the suprascapular notch (Fig. 46.3B). Near the suprascapular notch it gives origin to the inferior belly of omohyoid. The notch is bridged by the superior transverse ligament which is attached laterally to the root of the coracoid process and medially to the limit of the notch. The ligament is sometimes ossified. The foramen, thus completed, transmits the suprascapular nerve to the supraspinous fossa, whereas the suprascapular vessels pass backwards above the ligament.

Lateral border

The lateral border of the scapula forms a clearly defined, sharp, roughened ridge,
which runs sinuously from the inferior angle to the glenoid cavity. At its upper end it widens into a rough, somewhat triangular area, which is termed the infraglenoid tubercle (Fig. 46.4B). The lateral border separates the attachments of subscapularis and teres minor and major. These muscles project beyond the bone and, with latissimus dorsi, cover it so completely that it cannot be felt through the skin. The long head of triceps is attached to the infraglenoid tubercle.

The grooved part of the costal surface, the narrow flat lateral strip of the dorsal surface and the adjacent thickened ridge (Fig. 46.4B), are often included in the 'lateral border' during clinical examination.

Medial border

The medial border of the scapula extends from the inferior to the superior angle. In its lower two-thirds this border can easily be felt through the skin, but its upper third is more deeply placed and cannot be palpated. It is thin and often angled opposite the root of the spine. Levator scapulae is attached to a narrow strip, extending from the superior angle to the root of the spine, and rhomboid minor is attached below this, opposite the root of the spine. Rhomboid major is attached to the remainder of the border.

Scapular angles

The inferior angle overlies the seventh rib or intercostal space. Palpable through the skin and covering muscles, it is also visible as it advances round the thoracic wall when the arm is raised. It is covered on its dorsal aspect by the upper border of latissimus dorsi, a small slip from which is frequently attached to the inferior angle. The superior angle, at the junction of the superior and medial borders, is obscured by the upper part of trapezius. The lateral angle, truncated and broad, bears the glenoid cavity which articulates with the head of the humerus at the glenohumeral joint. It provides a shallow, and limited, socket for the humeral head. Its outline is piriform, narrower above (Fig. 46.4B). The glenohumeral ligaments are attached to its anterior margin. When the arm is by the side, the cavity is directed forwards, laterally and slightly upwards. When the arm is raised above the head it is directed almost straight upwards. Just above it a small rough supraglenoid tubercle encroaches on the root of the coracoid process. The anatomical neck, the constriction adjoining the rim of the glenoid cavity, is most distinct at its inferior and dorsal aspects. Anteriorly and posteriorly it extends between the infraglenoid and supraglenoid tubercles, passing lateral to the root of the coracoid process. The long head of biceps brachii is attached to the supraglenoid tubercle, and the long head of triceps brachii is attached to the infraglenoid tubercle.

Spine of the scapula

The spine of the scapula forms a shelf-like projection on the upper part of the dorsal surface of the bone, and is triangular in shape (Fig. 46.3A). Its lateral border is free, thick and rounded and helps to bound the spinoglenoid notch, which lies between it and the dorsal surface of the neck of the bone. Its anterior border joins the dorsal surface of the scapula along a line which runs laterally and slightly upwards from the junction of the upper and middle thirds of the medial border. The plate-like body of the bone is bent along this line, which accounts for the concavity of the upper part of the costal surface. The dorsal border is the crest of the spine, and is subcutaneous.
throughout nearly its whole extent. At its medial end the crest expands into a smooth, triangular area. Elsewhere the upper and lower edges and the surface of the crest are roughened for muscular attachments. The upper surface of the spine widens as it is traced laterally, and is slightly hollowed out. Together with the upper area of the dorsal surface of the bone, the upper surface of the spine forms the supraspinous fossa. The lower surface is overhung by the crest at its medial, narrow end, but is gently convex in its wider, lateral portion. Together with the lower area of the dorsal surface of the bone, the lower surface of the spine forms the infraspinous fossa, which communicates with the supraspinous fossa through the spinoglenoid notch.

Supra- and infraspinatus are attached to the upper and lower surfaces of the spine of the scapula, respectively. The flattened triangular area at its root lies opposite the spine of the third thoracic vertebra and is covered by the tendon of trapezius; a bursa intervenes to enable the tendon to play over this part of the bone. The posterior fibres of deltoïd are attached to the lower border of the crest. The middle fibres of trapezius are attached to the upper border of the crest, and the lowest fibres of trapezius terminate in a flat triangular tendon which glides over the smooth area at the base of the spine and inserts into a rough prominence, erroneously called the deltoïd tubercle, on the dorsal or subcutaneous aspect of the spine near its medial end.

**Acromion**

The acromion projects forwards, almost at right angles, from the lateral end of the spine, with which it is continuous. The lower border of the crest of the spine becomes continuous with the lateral border of the acromion at the acromial angle, which forms a subcutaneous, bony landmark. The medial border of the acromion is short and is marked anteriorly by a small, oval facet, directed upwards and medially, for articulation with the lateral end of the clavicle. The lateral border, tip and upper surface of the acromion can all be felt through the skin without difficulty. There may be an accessory articular facet on the inferior surface of the acromion.

The acromion is subcutaneous over its dorsal surface, being covered only by the skin and superficial fascia. The lateral border, which is thick and irregular, and the tip of the process, as far round as the clavicular facet, give origin to the middle fibres of deltoïd. The medial aspect of the tip gives attachment, below deltoïd, to the lateral end of the coraco-acromial ligament. The articular capsule of the acromioclavicular joint is attached around the margins of the clavicular facet. Behind the facet, the medial border of the acromion gives insertion to the horizontal fibres of trapezius. The inferior aspect of the acromion is relatively smooth, and together with the coraco-acromial ligament and the coracoid process forms a protective arch over the shoulder joint. The tendon of supraspinatus passes below the overhanging acromion and is separated from it and from deltoïd by the subacromial bursa.

**Coracoid process**

The coracoid process arises from the upper border of the head of the scapula and is bent sharply so as to project forwards and slightly laterally (Fig. 46.3B, Fig. 46.4A). When the arm is by the side, the coracoid process points almost straight forwards and its slightly enlarged tip can be felt through the skin, although it is covered by the anterior fibres of deltoïd. The supraglenoid tubercle marks the root of the coracoid process where it adjoins the upper part of the glenoid cavity. There is another
impression on the dorsal aspect of the coracoid process at the point where it changes
direction: it gives attachment to the conoid part of the coracoclavicular ligament.

The coracoid process lies about 2.5 cm below the clavicle at the junction of the lateral
fourth with the rest of the bone and is connected to its under surface by the
coracoclavicular ligament. It is covered by the anterior fibres of deltoid and can be
identified only on deep pressure through the lateral border of the infraclavicular fossa.
The attachment of the conoid part of the ligament has already been considered: the
trapezoid part is attached to the upper aspect of the horizontal part of the process.
Pectoralis minor is attached to the superior aspect of the coracoid process. The wider,
medial end of the coraco-acromial ligament and, below that, the coracohumeral
ligament, are attached to the lateral border. Coracobrachialis is attached to the medial
side of the tip of the process, and the short head of biceps is attached to the lateral
side of the tip. The inferior aspect of the process is smooth and helps to complete the
coraco-acromial arch.

Ligaments

The main scapular ligaments are the coracoacromial and superior transverse
scapular; there may also be a weaker, variable inferior transverse scapular
.spinoglenoid) ligament (see below Fig. 46.13, see below Fig. 46.14).
Fig. 46.13 Interior of the left shoulder joint: anterolateral aspect. (From Sobotta 2006.)
Coracoacromial ligament

The coracoacromial ligament is a strong triangular band between the coracoid process and acromion. It is attached apically to the acromion anterior to its clavicular articular surface and by its base along the whole lateral border of the coracoid. Together with the coracoid process and acromion it completes an arch above the humeral head. It may be composed of two strong marginal bands with a thinner centre; when pectoralis minor is inserted into the humeral capsule instead of the coracoid process, which happens occasionally, its tendon passes between the bands. The subacromial bursa facilitates movement between the coracoacromial arch and the subjacent supraspinatus and shoulder joint, functioning as a secondary synovial articulation.

Inferior transverse scapular (spinoglenoid) ligament

When present, the inferior transverse scapular ligament is a membranous ligament which may stretch from the lateral border of the spine of the scapula to the glenoid margin. It forms an arch over the suprascapular nerve and vessels entering the infraspinous fossa.

Ossification

The cartilaginous scapula is ossified from eight or more centres: one in the body, two each in the coracoid process and the acromion, one each in the medial border, inferior angle and lower part of the rim of the glenoid cavity (Fig. 46.5). The centre for the
body appears in the eighth intrauterine week. Ossification begins in the middle of the coracoid process in the first year or in a small proportion of individuals before birth and the process joins the rest of the bone about the 15th year. At or soon after puberty centres of ossification occur in the rest of the coracoid process (subcoracoid centre), in the rim of the lower part of the glenoid cavity, frequently at the tip of the coracoid process, in the acromion, in the inferior angle and contiguous part of the medial border and in the medial border. A variable area of the upper part of the glenoid cavity, usually the upper third, is ossified from the subcoracoid centre; it unites with the rest of the bone in the 14th year in the female and the 17th year in the male. A horse-shoe shaped epiphysis appears for the rim of the lower part of the glenoid cavity; thicker at its peripheral than at its central margin, it converts the flat glenoid cavity of the child into the gently concave fossa of the adult. The base of the acromion is formed by an extension from the spine; the rest of the acromion is ossified from two centres which unite and then join the extension from the spine. The various epiphyses of the scapula have all joined the bone by about the 20th year.
Fig. 46.5  Ossification of the scapula. A, Dorsal aspect; B, Lateral aspect.
(Adapted from Drake, Vogl and Mitchell 2005.)
HUMERUS

The humerus, the longest and largest bone in the upper limb, has expanded ends and a shaft (Fig. 46.6, Fig. 46.7, Fig. 46.8). The rounded head occupies the proximal and medial part of the upper end of the bone and forms an enarthrodial articulation with the glenoid cavity of the scapula. The lesser tubercle projects from the front of the shaft, close to the head, and is limited on its lateral side by a well-marked groove. The distal end, loosely termed ‘condylar’, is adapted to the forearm bones at the elbow joint.

The capsular ligament of the elbow joint is attached anteriorly to the upper limits of the radial and coronoid fossae, so that both these bony depressions are intracapsular and therefore lined with synovial membrane. Medially it is attached to the medial non-articular aspect of the projecting lip of the trochlea and to the root of the medial epicondyle. Posteriorly it ascends to, or almost to, the upper margin of the olecranon fossa, which is therefore intracapsular and covered with synovial membrane. Laterally it skirts the lateral borders of the trochlea and capitulum, lying medial to the lateral epicondyle.

With the arm by the side, the medial epicondyle lies on a plane which is posterior to that of the lateral epicondyle, so that the humerus appears to be rotated medially. In this position the head of the humerus is directed almost equally backwards and medially, and the posterior surface of the shaft faces posterolaterally. Since the glenoid fossa of the scapula faces anterolaterally, the humerus is not rotated medially relative to the scapula in this position of rest, but it is so rotated relative to the conventional anatomical position. This position of the bone must be remembered when movements of the arm and forearm are considered.

**Proximal end**

The proximal end of the humerus consists of the head, anatomical neck and the greater and lesser tubercles. It joins the shaft at an ill-defined 'surgical neck', which is closely related on its medial side to the axillary nerve and posterior humeral circumflex artery (Fig. 46.7).

**Head**

The head of the humerus forms rather less than half a spheroid; in sectional profile it is spheroidal (strictly ovoidal) (Fig. 46.7). Its smooth articular surface is covered with hyaline cartilage, which is thicker centrally. When the arm is at rest by the side, it is directed medially, backwards and upwards to articulate with the glenoid cavity of the scapula. The humeral articular surface is much more extensive than the glenoid
cavity, and only a portion of it is in contact with the cavity in any one position of the arm.

**Anatomical neck**

The anatomical neck of the humerus immediately adjoins the margin of the head and forms a slight constriction, which is least apparent in the neighbourhood of the greater tubercle, and superorly, and for some distance anteriorly and posteriorly: it indicates the line of capsular attachment of the shoulder joint (Fig. 46.7), other than at the intertubercular sulcus, where the long tendon of biceps emerges. Medially, the capsular attachment diverges from the anatomical neck and descends 1 cm or more onto the shaft.

**Lesser tubercle**

The lesser tubercle is anterior to and just beyond the anatomical neck. It has a smooth, muscular impression on its upper part palpable through the thickness of deltoid 3 cm below the acromial apex. The bony prominence slips away from the examining finger when the humerus is rotated. The lateral edge of the lesser tubercle is sharp and forms the medial border of the intertubercular sulcus. Subscapularis is attached to the lesser tubercle (Fig. 46.6A), and the transverse ligament of the shoulder joint is attached to the lateral margin.

**Greater tubercle**

The greater tubercle is the most lateral part of the proximal end of the humerus. It projects beyond the lateral border of the acromion. Its posterosuperior aspect, near the anatomical neck, bears three smooth flattened impressions for the attachment of supraspinatus (uppermost), infraspinatus (middle) and teres minor (lowest and placed on the posterior surface of the tubercle) (Fig. 46.6). The attachments of subscapularis and teres minor are not confined to their respective tubercles, but extend for varying distances on to the adjacent metaphysis. The projecting lateral surface of the tubercle presents numerous vascular foramina and is covered by the thick, fleshy deltoid, which produces the normal rounded contour of the shoulder. A part of the subacromial bursa may cover the upper part of this area and separate it from deltoid.

The intertubercular sulcus (bicipital groove) lies between the tubercles. It contains the long tendon of biceps, its synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The rough lateral lip of the groove is marked by the bilaminar tendon of pectoralis major, its floor by the tendon of latissimus dorsi and its medial lip by the tendon of teres major; the attachment of pectoralis major extends beyond that of teres major, that of latissimus dorsi is least extensive.

**Shaft**

The shaft of the humerus is almost cylindrical in its proximal half but is triangular on section in its distal half, which is compressed in an anteroposterior direction. It can be identified when the arm is grasped firmly, but its outline is obscured by the strong muscles which surround it. It has three surfaces and three borders – which are not everywhere equally obvious.

**Anterior border**
The anterior border starts on the front of the greater tubercle and runs downwards almost to the lower end of the bone. Its proximal third forms the lateral lip of the intertuberculous sulcus and is roughened for muscular attachments. The succeeding portion is also roughened and forms the anterior limit of the deltoid tubercle; the lower half of the border is smooth and rounded.

**Lateral border**

The lateral border is conspicuous at the lower end of the bone, where it is thickened to form the lateral supracondylar ridge and its sharp edge is roughened along its anterior aspect. In its middle and upper thirds the border is barely discernible, but in a well-marked bone it can be traced upwards to the posterior surface of the greater tubercle. A little above its middle it is marked by a V-shaped roughened area, the deltoid tubercle. The limbs of the V are broad: the groove for the radial nerve runs downwards behind the posterior limb and fades away on the lower part of the surface.

**Medial border**

The medial border, although rounded, can be identified without difficulty in the lower half of the shaft, where it becomes the medial supracondylar ridge. In the proximal third the medial border is indistinct until it reappears as the medial lip of the intertubercular sulcus, where it is again rough and reaches the lesser tubercle. In its middle third, the border is interrupted by a wide, shallow groove, the radial or spiral groove, which crosses the bone obliquely, passing downwards and forwards from its posterior to its anterior surface.

**Surfaces**

The anterolateral surface is bounded by the anterior and lateral borders and is smooth and featureless in its upper part, which is covered by deltoid. About, or a little above, the middle of this surface, deltoid is inserted into the deltoid tubercle; further distally the surface gives origin to the lateral fibres of brachialis, which extend upwards into the floor of the lower end of the groove for the radial nerve (Fig. 46.6). Brachioradialis is attached to the proximal two-thirds of the roughened anterior aspect of the lateral supracondylar ridge, and extensor carpi radialis longus is attached to its distal third. Behind these muscles, the ridge gives attachment to the lateral intermuscular septum of the arm.

The anteromedial surface is bounded by the anterior and medial borders. Rather less than its upper third forms the rough floor of the intertubercular sulcus; the rest of the surface is smooth. Distal to the intertubercular sulcus a small area of the anteromedial surface is devoid of muscular attachment, but its lower half is occupied by the medial part of brachialis (Fig. 46.6A). Coracobrachialis is attached to a roughened strip on the middle of the medial border. The humeral head of pronator teres is attached to a narrow area close to the lowest part of the medial supracondylar ridge, and the ridge itself gives attachment to the medial intermuscular septum of the arm.

A little below its midpoint, the nutrient foramen, which is directed downwards, opens close to the medial border. A hook-shaped process of bone, the supracondylar process, from 2 to 20 mm in length, occasionally projects from the anteromedial surface of the shaft, approximately 5 cm proximal to the medial epicondyle. It is curved downwards and forwards, and its pointed apex is connected to the medial
border, just above the epicondyle, by a fibrous band to which part of pronator teres is attached. The foramen completed by this fibrous band usually transmits the median nerve and brachial artery, but sometimes encloses only the nerve, or the nerve plus the ulnar artery (in cases of high division of the brachial artery). A groove which lodges the artery and nerve usually exists behind the process, and may protect the nerve and artery from compression by muscles.

The posterior surface, between the medial and lateral borders, is the most extensive surface and is occupied mostly by the medial head of triceps. A ridge, sometimes rough, descends obliquely and laterally across its proximal third, and gives attachment to the lateral head of triceps. Above triceps, the axillary nerve and the posterior circumflex humeral vessels wind round this aspect of the bone under cover of deltoid. Below and medial to the attachment of the lateral head of triceps, a shallow groove which contains the radial nerve and the profunda brachii vessels, runs downwards and laterally to gain the anterolateral surface of the shaft. The area for the origin of the fleshy medial head of triceps includes a very large part of the posterior surface of the bone. It covers an elongated triangular area, the apex of which is placed on the medial part of the posterior surface above the level of the lower limit of the insertion of teres major. The area widens below and covers the whole surface almost down to the lower end of the bone.

**Fractures of the humeral shaft**

Fractures of the humerus are comparatively common and may occur at almost any level. The humerus is fractured by muscular action probably more frequently than any other long bone: usually the shaft is broken below the attachment of deltoid. The radial nerve may be injured in its groove or may very rarely become involved later in the growth of callus. Fractures at the proximal end of the humerus may rarely damage the axillary nerve, and similarly fractures of the medial epicondyle may be complicated by damage to the ulnar nerve. Supracondylar fractures are relatively common in children: the end of the proximal fragment can sometimes injure the brachial artery or median nerve. In adults, non-union is more common in the humerus than in any other long bone, although contemporary management of humeral fractures has rendered non-union rare: the incidence of scaphoid non-union is similar, if not greater.

**Distal end**

The distal end of the humerus is a modified condyle: it is wider transversely and has articular and non-articular parts (Fig. 46.8, Fig. 46.9). The articular part is curved forwards, so that its anterior and posterior surfaces lie in front of the corresponding surfaces of the shaft. It articulates with the radius and the ulna at the elbow joint, and is divided by a faint groove into a lateral capitulum, and a medial trochlea.
The capitulum is a rounded, convex projection, considerably less than half a sphere, which covers the anterior and inferior surfaces of the lateral part of the condyle of the humerus but does not extend onto its posterior surface. It articulates with the discoid head of the radius, which lies in contact with its inferior surface in full extension of the elbow but slides onto its anterior surface during flexion. The groove of the trochlea winds backwards and laterally as it is traced from the anterior to the posterior surface of the bone, and it is wider, deeper and more symmetrical posteriorly. Anteriorly, the medial flange of the pulley is much longer than the lateral, and the surface adjoining its projecting medial margin is convex to accommodate itself to the medial part of the upper surface of the coronoid process of the ulna. These asymmetries entail varying angulation between the humeral and ulnar axes, together with some conjunct rotation. The non-articular part of the condyle includes the medial and lateral epicondyles, olecranon and coronoid and radial fossae.

**Trochlea**

The trochlea is a pulley-shaped surface that covers the anterior, inferior and posterior surfaces of the condyle of the humerus medially. It articulates with the trochlear notch of the ulna. On its lateral side it is separated from the capitulum by a faint groove; its medial margin projects distally beyond the rest of the bone. When the elbow is extended the inferior and posterior aspects of the trochlea are in contact with the ulna, but, as the joint is flexed, the trochlear notch slides on to the anterior aspect and the
posterior aspect is then left uncovered. The downward projection of the medial edge of the trochlea is the principal factor in determining the angulation between the long axis of the humerus and the long axis of the supinated forearm when the elbow is extended.

Medial epicondyle

The medial border of the humerus ends by turning slightly backwards as the medial epicondyle, which forms a conspicuous, blunt projection on the medial side of the condyle. It is subcutaneous and usually visible, especially in passive flexion of the elbow. Its posterior surface is smooth and is crossed by the ulnar nerve, which lies in a shallow sulcus as it enters the forearm. In this situation the nerve can be felt and rolled against the bone, and if it is jarred against the epicondyle, characteristic tingling sensations result. The lower part of the anterior surface of the medial epicondyle is marked by the attachment of the superficial group of forearm flexors. They arise from the epiphysis for the epicondyle, but are entirely extracapsular.

Lateral epicondyle

The lateral border of the humerus terminates at the lateral epicondyle, and its lower portion constitutes the lateral supracondylar ridge. The lateral epicondyle occupies the lateral part of the non-articular portion of the condyle, but does not project beyond the lateral supracondylar ridge. It turns slightly forwards, unlike the medial epicondyle, which turns slightly backwards. Its lateral and anterior surfaces show a well-marked impression for the superficial group of the extensor muscles of the forearm (Fig. 46.6B), which arise from the lateral side of the lower humeral epiphysis, and, like the flexors, are situated outside the articular capsule. The posterior surface, which is very slightly convex, is easily felt in a depression visible behind the extended elbow. A small area on the posterior surface gives origin to anconeus.

Olecranon, coronoid and radial fossae

The olecranon fossa is a deep hollow on the posterior surface of the condyle, immediately above the trochlea, that lodges the tip of the olecranon of the ulna when the elbow is extended. The floor of the fossa is always thin and may be partially deficient. A similar but smaller hollow lies immediately above the trochlea on the anterior surface of the condyle and is termed the coronoid fossa. It accommodates the anterior margin of the coronoid process of the ulna during flexion of the elbow. A very slight depression lies above the capitulum on the lateral side of the coronoid fossa. It is termed the radial fossa, since it is related to the margin of the head of the radius in full flexion of the elbow.

Ossification

The humerus is ossified from eight centres, in the shaft, head, greater and lesser tubercles, capitulum with the lateral part of the trochlea, the medial part of the trochlea, and one for each epicondyle (Fig. 46.10). The centre for the shaft appears near its middle in the eighth week of intrauterine life, and gradually extends towards the ends. Before birth (20%), or in the first six months afterwards, ossification begins in the head, during the first year in females and second year in males in the greater tubercle, and about the fifth in the lesser tubercle. The existence of a centre in the lesser tubercle is often questioned, perhaps because it is often obscured in the usual
anteroposterior radiological views (Fig. 46.11).

Fig. 46.10 The stages in ossification of the humerus (not to scale).
By the sixth year the centres for the head and tubercles have joined to form a single large epiphysis, which is hollowed out on its inferior surface to adapt it to the somewhat conical upper end of the metaphysis. It fuses with the shaft of the humerus about the twentieth year in males, two years earlier in females. The lower end is ossified as follows. During the first year ossification begins in the capitulum and extends medially to form the chief part of the articular surface; the centre for the medial part of the trochlea appears in the ninth year in females and tenth year in males.

Ossification begins in the medial epicondyle in the fourth year in females, sixth in males, and in the lateral epicondyle about the 12th year. The centres for the lateral
epicondyle, capitulum and trochlea fuse around puberty and the composite epiphysis unites with the shaft in the fourteenth year in females, sixteenth in males. The centre for the medial epicondyle forms a separate epiphysis, which is entirely extracapsular and is placed on the posteromedial aspect of the epicondyle. It is separated from the rest of the lower epiphysis by a downgrowth from the shaft, with which it unites about the 20th year.

**Amputation of the humerus in youth**

The proximal epiphysis joins the humeral shaft later than the distal, which means that growth in length is mainly attributable to growth from the proximal epiphysial plate. After amputation through the arm in youth, the humerus continues to grow and its lower end progressively moulds the surrounding soft tissues so that the stump becomes conical.
JOINTS

STERNOCLAVICULAR JOINT

The sternoclavicular joint is a synovial sellar joint and represents the only skeletal articulation between the upper limb and the axial skeleton.

Articulating surfaces

The articulating surfaces are the sternal end of the clavicle and the clavicular notch of the sternum, together with the adjacent superior surface of the first costal cartilage (Fig. 46.12). The larger clavicular articular surface is covered by fibrocartilage, which is thicker than the fibrocartilaginous lamina on the sternum. The joint is convex vertically but slightly concave anteroposteriorly, and is therefore sellar; the clavicular notch of the sternum is reciprocally curved, but the two surfaces are not fully congruent. An articular disc completely divides the joint.

![Fig. 46.12 Sternoclavicular joints: anterior aspect; left joint intact and right in coronal section.](image)

Fibrous capsule

The capsule is thickened in front and behind, but above, and especially below, it is little more than loose areolar tissue.

Ligaments

The ligaments are the anterior and posterior sternoclavicular and the costoclavicular on each side, and the midline interclavicular.

*Anterior sternoclavicular ligament*
The anterior sternoclavicular ligament is broad and attached above to the anterosuperior aspect of the sternal end of the clavicle. It passes inferomedially to the upper anterior aspect of the manubrium, spreading onto the first costal cartilage.

**Posterior sternoclavicular ligament**

The posterior sternoclavicular ligament is a weaker band posterior to the joint. It descends inferomedially from the back of the sternal end of the clavicle to the back of the upper manubrium.

**Interclavicular ligament**

The interclavicular ligament is continuous above with deep cervical fascia, and unites the superior aspect of the sternal ends of both clavicles; some fibres are attached to the superior manubrial margin.

**Costoclavicular ligament**

The costoclavicular ligament is like an inverted cone, but short and flattened. It has anterior and posterior laminae which are attached to the upper surface of the first rib and costal cartilage, and ascends to the margins of an impression on the inferior clavicular surface at its medial end. Fibres of the anterior lamina ascend laterally and those of the posterior lamina (which are shorter) ascend medially (Fig. 46.12); they fuse laterally and merge medially with the capsule.

**Articular disc**

The articular disc is flat and almost circular, between the sternal and clavicular surfaces. It is attached above to the posterosuperior border of the articular surface of the clavicle, below to the first costal cartilage near its sternal junction, and by the rest of its circumference to the capsule. It is thicker peripherally, especially in its superoposterior part and a smaller inferomedial one. The capsule around the former is more lax: movements between the clavicle and the disc are more extensive than those between the disc and sternum. The sellar shape of the articular surfaces permits movement in approximately anteroposterior and vertical planes, and some rotation about the long axis of the clavicle. Close-packing probably coincides with maximum posterior rotation associated with full scapular rotation. Some anteroposterior translation also occurs.

**Vascular supply**

The sternoclavicular joint is supplied by branches from the internal thoracic and suprascapular arteries.

**Innervation**

The sternoclavicular joint is innervated by branches from the medial supraclavicular nerve and the nerve to subclavius.

**Factors maintaining stability**

There is relatively little bony articular congruence at the sternoclavicular joint. However, the strength of its associated ligaments, and especially its articular disc,
actually make it very stable. These factors, and the usual transmission of forces along
the clavicle, make dislocation rare: fracture along the clavicular shaft is far more
common.
ACROMIOCLAVICULAR JOINT

The acromioclavicular joint is a synovial plane joint.

Articulating surfaces

The articulating surfaces are between the acromial end of the clavicle and the medial acromial margin (Fig. 46.13). The joint is approximately plane, but either surface may be slightly convex, the other being reciprocally concave, and both are covered by fibrocartilage. The clavicular surface is a narrow, oval area which faces inferolaterally and overlaps a corresponding facet on the medial acromial border. The long axis is anteroposterior.

Fibrous capsule

The capsule completely surrounds the articular margins and is strengthened above by the acromioclavicular ligament. The capsule is lined by synovial membrane.

Ligaments

The acromio- and coraco-clavicular ligaments run between the clavicle and the acromion and coracoid processes respectively.

Acromioclavicular ligament

The acromioclavicular ligament is quadrilateral. It extends between the upper aspects of the lateral end of the clavicle and the adjoining acromion. Its parallel fibres interlace with the aponeuroses of trapezius and deltoid.

Coracoclavicular ligament

The coracoclavicular ligament connects the clavicle and the coracoid process of the scapula (Fig. 46.14). Though separate from the acromioclavicular joint, it is a most efficient accessory ligament, and maintains the apposition of the clavicle to the acromion. The trapezoid and conoid parts of the ligament, usually separated by fat or, frequently, by a bursa, connect the medial horizontal part of the coracoid process and lateral end of the subclavian groove of the clavicle; these adjacent areas may even be covered by cartilage to form a coracoclavicular joint.

The trapezoid part is anterolateral and is broad, thin and quadrilateral, ascending slightly from the upper coracoid surface to the trapezoid line on the inferior clavicular surface. It is almost horizontal, its anterior border is free, and its posterior border is joined to the conoid part, forming an angle which projects backwards.
The conoid part is posteromedial and is a dense, almost vertical triangular band. Its base is attached to the conoid tubercle of the clavicle and its inferior apex is attached posteromedially to the root of the coracoid process in front of the scapular notch.

Articular disc

The articular disc often occurs in the upper part of the joint, partially separating the articular surfaces: occasionally it completely divides the joint.

Vascular supply

The acromioclavicular joint receives its arterial supply from branches from the suprascapular and thoracoacromial arteries.

Innervation

The acromioclavicular joint is innervated by branches from the suprascapular and lateral pectoral nerves.

Factors maintaining stability

The coracoclavicular ligament stabilizes the acromioclavicular joint. In acromioclavicular dislocation, the ligament is torn and the scapula falls away from the clavicle, which may be slightly elevated by the unopposed pull of trapezius. Dislocation can occur because of the flatness and orientation of the joint surfaces; once the acromioclavicular joint dislocates it never reduces.

Movements

Movements at the joint are like those of the sternoclavicular joint. These are passive, i.e. no muscle directly moves the joint, but muscles which move the scapula indirectly move the clavicle. Axial rotation of the clavicle is about 30°, the two joints together therefore, permit about 60° of scapular rotation. Angulation with the scapula occurs in any direction.
MOVEMENTS OF THE PECTORAL (SHOULDER) GIRDLE

Clavicular movements at the sternoclavicular and acromioclavicular joints are inevitably associated with movements of the scapula, and these are usually accompanied by movements of the humerus. The acromioclavicular joint allows anteroposterior gliding and rotation of the acromion, and hence the scapula, on the clavicle: scapular range is increased by movements at the sternoclavicular joint. The sternoclavicular and the acromioclavicular joints, in combination with the fascial space between the scapula and underlying chest wall, are collectively known as the scapulothoracic articulation.

In all scapular movements, it is assumed that subclavius probably steadies the clavicle by drawing it medially and downwards, although its inaccessibility for electromyographic analysis makes its role uncertain. Scapular movements on the thoracic wall are facilitated by areolar tissue between subscapularis, serratus anterior and the chest wall. With the arm by the side, the normal posture of the shoulder girdle relative to the trunk involves moderate activity in trapezius and serratus anterior, and this increases when the limb is loaded.

The following account should be read together with the description of movements of the glenohumeral joint.

Elevation and depression

Scapular elevation and depression, as in ‘shrugging the shoulders’, do not necessarily imply movement at the shoulder joint. In elevation, slight angulation or swing occurs at the acromioclavicular joint. The sternal end of the clavicle, rotating about an anteroposterior axis through the bone above the medial attachment of the costoclavicular ligament, slides down over the articular disc (translation). This is checked by antagonist muscles and tension in the costoclavicular ligament and lower capsule. It is produced by the upper part of trapezius and levator scapulae, and since these tend to rotate the scapula in opposite directions, pure elevation can occur. In depression, slight angulation occurs at the acromioclavicular joint, and the clavicle slides up on the disc at the sternoclavicular joint. The movements are checked by antagonist muscles, the interclavicular and sternoclavicular ligaments and the articular disc. Usually gravity alone is sufficient: when necessary, the lowest part of serratus anterior and pectoralis minor are active depressors.

Protraction and retraction

Protraction (forward movement) round the thoracic wall occurs in pushing, thrusting and reaching movements, usually with some lateral rotation. The acromion advances over the clavicular facet to the limit, and the shoulder is simultaneously advanced by forward movement of the lateral end of the
clavicle and posterior translation of its sternal end over the sternal facet, carrying the disc with it. Antagonist muscles, together with the anterior sternoclavicular ligament and posterior lamina of the costoclavicular ligament, check backward slide of the sternal end. Serratus anterior and pectoralis minor are prime movers and maintain continuous apposition of the scapula, especially its medial border, in smooth gliding on the thoracic wall. The upper part of latissimus dorsi also acts like a strap across the inferior scapular angle in protraction and lateral rotation.

In scapular retraction, i.e. bracing back the shoulders, these movements are reversed and checked at the sternoclavicular joint by the posterior sternoclavicular ligament and anterior lamina of the costoclavicular ligament. Trapezius and the rhomboids are prime movers, but gravity may also produce retraction when the weight of the trunk is taken by the arms in leaning forwards, which is to a degree controlled by protractive musculature.

When force is applied at the end of an outstretched arm, e.g. in a fall on the hand, pressure transmitted to the glenoid fossa tends to drive the sloping acromial facet below the acromial end of the clavicle. It also tenses the trapezoid ligament, which resists the displacement.

**Lateral and medial rotation**

Lateral (upward) rotation of the scapula increases the range of humeral elevation by turning the glenoid cavity to face almost directly up, e.g. raising an arm above the head. This movement is always associated with some humeral elevation and with protraction of the scapula. Scapular rotation requires movement at both sternoclavicular and acromioclavicular joints: the sternoclavicular joint permits elevation of the lateral end of the clavicle, a movement which is almost complete when the arm is abducted to 90°. The acromioclavicular joint moves in the first 30° of abduction, when the conoid ligament becomes taut, and is subsequently accompanied by clavicular rotation at the sternoclavicular joint around the longitudinal axis of the bone. The medial end is depressed further as the lateral end continues to rise. Some acromioclavicular movement also occurs in the final stages of humeral abduction. Trapezius (upper part) and serratus anterior (lower part) are prime movers.

Medial (downward) rotation is usually effected by gravity: gradual active lengthening of trapezius and serratus anterior is sufficient to control it. When more force is needed, levator scapulae, the rhomboids and, in the initial stages, pectoralis minor, are prime movers in returning the scapula to a position of rest.

Muscles which are antagonists in one movement may combine as prime movers in another. Movements, not muscles, are represented in cerebral
motor areas. Muscles are not grouped unalterably in nervous control but can be variably combined as demands dictate. Thus serratus anterior and trapezius are opposed in scapular movement round the thorax, but combine as prime movers in lateral rotation of the scapula.
GLENOHUMERAL (SHOULDER) JOINT

The glenohumeral joint is a synovial multiaxial spheroidal joint between the roughly hemispherical head of the humerus and the shallow glenoid fossa of the scapula (Fig. 46.15). Notable for its relative lack of bony constraint, the joint possesses three degrees of freedom. Its static and dynamic stability depends on the surrounding muscular and soft tissue envelope more than on its shape and ligaments: effective function is achieved by a complex interaction between the articular and soft tissue restraints. It is the most mobile joint in the body and the most frequently dislocated.

Fig. 46.15  Radiographs of the left shoulder of an 18 year old female in anteroposterior view (A) and axillary view with the arm abducted (B). 1. Head of humerus. 2. Acromion. 3. Clavicle. 4. Acromioclavicular joint. 5. Coracoid. 6. Glenoid. 7. Glenohumeral articulation.

Articulating surfaces
The articular surfaces are reciprocally curved and are really ovoids. (Here, as in the hip, where ovoid surfaces are almost spherical they are often termed spheroidal.) The area of the humeral convexity exceeds that of the glenoid concavity such that only a small portion opposes the glenoid in any position (Fig. 46.16). The remaining capitular articular surface is in contact with the capsule, so that contact on the glenoid fossa is much more uniformly distributed over its entire articular surface. The radius of curvature of the glenoid fossa in the coronal plane is greater than that of the humeral head, and is deepened by a fibrocartilaginous rim, the glenoid labrum (Fig. 46.13, Fig. 46.17). Both articular surfaces are covered by hyaline cartilage, which is thickest centrally and thinner peripherally over the humerus, and the reverse in the glenoid cavity. In most positions, their curvatures are not fully congruent, and the joint is loose-packed. Close packing (full congruence) is reached with the humerus abducted and laterally rotated (Fig. 5.61).

Fig. 46.16 Coronal sections through the left shoulder joint viewed from the posterior aspect. A, Anteriorly placed coronal section to show tendon of biceps, long head. B, Posteriorly placed coronal section to show subacromial bursa and contents
of quadrangular space.

(From Sobotta 2006.)

Glenoid labrum

The glenoid labrum is a fibrocartilaginous rim around the glenoid fossa. It is triangular in section and varies in size and thickness; its base is attached to the margin of the fossa and its free inner edge projects as a continuation of the curve of the glenoid. It blends above with two fasciculi from the long tendon of biceps. The labrum deepens the cavity, may protect the bone, and probably assists lubrication. Its attachment is
sometimes partly deficient anterosuperiorly, in which case synovial membrane may protrude through the gaps.

**Fibrous capsule**

A fibrous capsule envelops the joint (Fig. 46.14, Fig. 46.16). It is attached medially to the glenoid neck outside the glenoid labrum, and encroaches on the coracoid process to include the attachment of the long head of biceps. The capsule often extends and attaches to the base of the coracoid and to the body of the scapula, forming anterior and posterior recesses. Laterally, it is attached to the anatomical neck of the humerus, i.e. near the articular margin, except inferomedially, where it descends more than 1 cm on the humeral shaft. It is so lax that the bones can be distracted for 2 or 3 cm, which accords with the very wide range of movement possible at the glenohumeral joint. However, such unnatural separation requires relaxation of the upper capsule by abduction.

The fibrous capsule is supported by the tendons of supraspinatus (above), infraspinatus and teres minor (behind), subscapularis (in front) and by the long head of triceps (below). The rotator interval is a medially based triangular area of uncovered capsule between the superior edge of subscapularis and the anterior edge of supraspinatus as these tendons pass on either side of the base of the coracoid: it may represent an area of weakness that increases instability in some shoulders. Triceps is separated from the capsule by the axillary nerve and posterior circumflex humeral vessels as they pass back from the axilla (Fig. 46.14). The capsule is least supported inferiorly, and subjected to the greatest strain in full abduction, when it is stretched tightly across the humeral head. It is strengthened anteriorly by extensions from the tendons of pectoralis major and teres major.

There are usually two or three openings in the capsule: below the coracoid process, connecting the joint to a bursa behind the tendon of subscapularis (anterior); between the humeral tubercles, transmitting the long tendon of biceps and its synovial sheath; connecting the joint to a bursa under the tendon of infraspinatus (posterior and inconstant).

**Ligaments**

The ligaments associated with the glenohumeral joint are the glenohumeral (superior, middle and inferior), coracohumeral and transverse humeral.

**Glenohumeral ligaments**

Three glenohumeral ligaments, only visible from within the joint, reinforce the capsule anteriorly and inferiorly (Fig. 46.18). They do not act as traditional ligaments (which carry a pure tensile force along their length), but become taut at varying positions of abduction and humeral rotation, acting as ‘check-reins’. Moreover, they do not have the strength characteristics of the ligaments at the knee. The superior glenohumeral ligament passes from the supraglenoid tubercle, just anterior to the origin of the long head of biceps, to the humerus near the proximal tip of the lesser tubercle on the medial ridge of the intertuberculous groove, the fovea capitis. It forms an anterior cover around the long head of biceps, and is part of the rotator interval. Together with the coracohumeral ligament it is an important stabilizer in the inferior direction, helping to keep the humeral head suspended (the coracohumeral ligament is more robust
than the superior glenohumeral ligament). The middle glenohumeral ligament arises from a wide attachment below the superior glenohumeral ligament, along the anterior glenoid margin as far as the inferior third of the rim, and passes obliquely inferolaterally, enlarging as it does, to attach to the lesser tubercle deep to the tendon of subscapularis, with which it blends. The width and thickness of this ligament may be as much as 2 cm and 4 mm respectively. It provides anterior stability at 45° and 60° abduction. The thicker and longer inferior glenohumeral ligament complex is a hammock-like structure with anchor points on the anterior and posterior sides of the glenoid. It arises from the anterior, middle and posterior margins of the glenoid labrum, below the epiphysial line, and passes anteroinferiorly to the inferior and medial aspects of the neck of the humerus. The anterior, superior edge of the inferior ligament is thickened as the superior band, and the diffuse thickening of the anterior part of the capsule to which it is attached is known as the axillary pouch. The anterior band of the inferior glenohumeral ligament is thought to be the primary static anterior stabilizer of the abducted and externally rotated glenohumeral joint. (For further details consult Burkart & Debski 2002.)
Coracohumeral ligament

The coracohumeral ligament is attached to the dorsolateral base of the coracoid process and extends as two bands, which blend with the capsule, to the greater and lesser tubercles (Fig. 46.14). Portions of the coracohumeral ligament form a tunnel for the biceps tendon on the anterior side of the joint. The rotator interval is reinforced by the coracohumeral ligament. It also blends inferiorly with the superior glenohumeral ligament.

Transverse humeral ligament

The transverse humeral ligament is a broad band which passes between the humeral tubercles, and is attached superior to the epiphysial line (Fig. 46.14). It converts the intertubercular sulcus into a canal, and acts as a retinaculum for the long tendon of biceps.

Synovial membrane

The synovial membrane lines the capsule and covers parts of the anatomical neck. The long tendon of biceps traverses the joint in a synovial sheath which continues into the intertubercular sulcus as far as the surgical neck of the humerus (Fig. 46.14, Fig. 46.16).

Bursae Many bursae adjoin the shoulder joint.

They are usually found between the tendon of subscapularis and the capsule, communicating with the joint between the superior and middle glenohumeral ligaments; on the superior acromial aspect; between the coracoid process and capsule; between teres major and the long head of triceps: anterior and posterior to the tendon of latissimus dorsi. The subacromial bursa, between deltoid and the capsule, does not communicate with the joint cavity but is prolonged under the acromion and coracoacromial ligament, and between them and supraspinatus: it appears to be attached, together with the subdeltoid fascia, to the acromion. Bursae sometimes occur behind coracobrachialis and between the tendon of infraspinatus and the capsule, occasionally opening into the joint.

Vascular supply

The glenohumeral joint is supplied by branches from the anterior and posterior circumflex humeral, suprascapular and circumflex scapular vessels.

Innervation

The glenohumeral joint is innervated mainly from the posterior cord of the brachial plexus. The capsule is supplied by the suprascapular nerve (posterior and superior parts), axillary nerve (anteroinferior) and the lateral pectoral nerve (anterosuperior).

Factors maintaining stability
The articulation between the relatively large humeral head and the shallow glenoid fossa allow a wide range of movement at the expense of providing an unstable bony complex. The anterior joint capsule is strong but lax. A variety of additional factors help to increase the stability of the joint: the glenoid labrum deepens the concavity of the articulating glenoid, the glenohumeral ligaments act as static stabilizers in certain positions, and there is a negative pressure within the joint. The coracoacromial arch (coracoid, acromion and coracoacromial ligament) prevents upward dislocation of the humerus. The tendons of subscapularis, supraspinatus, infraspinatus and teres minor fuse with the lateral part of the joint capsule to form the ‘rotator cuff’. These short muscles collectively produce a compressive force during active glenohumeral movements which maintains congruent contact between the head of the humerus and the glenoid fossa, helps to resist skid, and checks excessive translation. The rotator cuff also provides strong lateral stability and prevents this part of the lax capsule from being nipped during joint movements. The long head of biceps offers additional superior support. The long head of triceps offers inferior support which is particularly important when the shoulder is abducted. However, the glenohumeral joint is least stable inferiorly when the shoulder is fully abducted.

 Movements at the shoulder (glenohumeral) joint

The shoulder is capable of any combination of swing and spin over a very wide range. Laxity of the capsule, and a humeral head which is large relative to a shallow glenoid fossa, afford a wider range of movement than at any other joint. Flexion–extension, abduction–adduction, circumduction and medial and lateral rotation all occur at the shoulder. Although the majority of the movement of the shoulder occurs at the glenohumeral joint, there is a varying contribution from the scapulothoracic articulation in most directions, most significantly in abduction, and excluding lateral rotation.

In analysis of shoulder movements it is preferable to refer humeral movement to the scapula, rather than to conventional anatomical planes (Fig. 46.19). When the arm hangs at rest the glenoid fossa faces almost equally forwards and laterally, and the humeral capitular and scapular (topographical) axes correspond, although the humerus, relative to the anatomical position, is medially rotated. Flexion carries the arm anteromedially on an axis through the humeral head orthogonal to the glenoid fossa at its centre. Abduction and adduction occur in a vertical plane orthogonal to that of flexion–extension; the axis is horizontal, through the humeral head, parallel with the glenoid plane. Pure abduction raises the arm anterolaterally in the plane of the scapula. However, when referred to the trunk, flexion and extension occur in the paramedian plane, and abduction and adduction in the coronal plane. In this sense, raising the arm vertically from flexion or raising it from abduction are both accompanied by humeral rotation in opposite directions. Whether ‘scapular’ or any other plane of abduction is described, these are selections from an infinite series. In scapular abduction points on the humeral surface pursue vertical cords but in rotation they are horizontal. In ‘pure’ flexion–extension, in a plane orthogonal to the scapula the axis of movement, and the notional ‘mechanical axis’, are regarded as projected from the centre of the glenoid cavity.
Glenohumeral abduction is approximately 90°, but angles up to 120° have been reported. Some 60° further abduction occurs at the sterno- and acromioclavicular articulations. Contralateral vertebral flexion also aids in bringing the arm to the vertical. During active elevation, movements at the glenohumeral and acromioclavicular joints are simultaneous, except in the initial few degrees, when most, often all, movement is glenohumeral. For every 15° of elevation, glenohumeral movement is said to be 10° and scapular movement 5°. During the initial stages of abduction, subscapularis, infraspinatus and teres minor counteract the strong upward component of pull of deltoid, which would otherwise cause the humeral head to slide up; the additive turning moments exerted by deltoid and supraspinatus about the shoulder joint can then abduct the arm.

In flexion, the humerus swings at right angles to the scapular plane and scapular rotation cannot increase the elevation (120°) obtainable in full flexion. If the fully flexed humerus is also abducted, elevation increases pro rata until, when the humerus reaches the scapular plane, i.e. when true abduction is reached, 180° of elevation becomes possible. In medial or lateral rotation, the humerus revolves about one-quarter of a circle around a vertical axis; the range is greatest when the arm is pendent, and least when it is vertical. When assessing the rotational range at the glenohumeral joint, the forearm should be flexed to a right angle at the elbow: this will prevent the effects of superadded pronation or supination in the pendent limb. In circumduction, which is a succession of the foregoing movements, the distal end of the humerus describes the base of a cone, its apex at the humeral head. This glenohumeral movement can be much increased by scapular movements, e.g. in acts of slinging objects with force.

The peculiar relation of the long head of biceps to the shoulder joint may serve several purposes. By its connection with both the shoulder and elbow, the muscle harmonizes their actions as an elastic ligament during all their movements. It helps to prevent the humeral head impinging on the acromion when deltoid contracts and to steady it in movements of the arm. In paralysis of supraspinatus it may also help
initiate abduction of the arm, particularly when the humerus is laterally rotated.

**Muscles producing movements**

The muscles which produce movements at the glenohumeral joint are principally deltoid, pectoralis major, latissimus dorsi and teres major. These long muscles all converge on the humerus, acting at mechanical advantage on a joint which, as a result of glenoid shallowness and capsular laxity, is relatively unstable. The long muscles are counteracted by the rotator cuff, a group of short muscles (subscapularis, supraspinatus, infraspinatus and teres minor) which are attached nearer to the joint, and which centre the head of the humerus in the glenoid fossa through the midrange of motion, when the capsuloligamentous structures are lax.

**Flexion**

Pectoralis major (clavicular part), deltoid (anterior fibres) and coracobrachialis assisted by biceps. The sternocostal part of pectoralis major is a major force in flexion forwards to the coronal plane from full extension.

**Extension**

Deltoid (posterior fibres) and teres major, from the dependent position. When the fully flexed arm is extended against resistance, latissimus dorsi and the sternocostal part of pectoralis major act powerfully until the arm reaches the coronal plane.

**Abduction**

Deltoid. Initially its effect is mainly upward and, unless opposed, this would displace the humerus upwards. Subscapularis, infraspinatus and teres minor exert downward traction and so apply an opposing force: together with deltoid they constitute a ‘couple’ to produce abduction in the scapular plane. Supraspinatus assists in effecting and maintaining this movement, but its precise role is controversial.

**Medial rotation**

Pectoralis major, deltoid (anterior fibres), latissimus dorsi, teres major and, with the arm pendent, subscapularis.

**Lateral rotation**

Infraspinatus, deltoid (posterior fibres) and teres minor. Lateral rotation is important for clearance of the greater tubercle and its associated tissues as it passes under the coracoacromial arch, as well as for relaxation of the capsular ligamentous constraints.

**Rotator cuff disease**

The subacromial space is defined inferiorly by the humeral head, and superiorly by the anterior edge and inferior surface of the anterior third of the acromion, coracoacromial ligament and acromioclavicular joint, forming the coracoacromial arch. It is occupied by the supraspinatus tendon, subacromial bursa, tendon of the long head of biceps brachii, and the capsule of the shoulder joint. Rotator cuff disease is a painful condition with a multifactorial aetiology in which severe or chronic impingement of the rotator cuff tendons on the undersurface of the coracacromial arch is often a
significant factor. The cuff normally impinges against the coracoacromial arch when the humerus is abducted, flexed and internally rotated. This is known as the impingement position. The supraspinatus tendon is anatomically affected most by the impingement, which interestingly also coincides with an area of reduced vascularity in this tendon. Severe impingement can be caused by thickening of the coracoacromial arch, by inflammation of the cuff from disorders such as rheumatoid arthritis, or as a result of prolonged overuse in the impingement position, e.g. in cleaning windows. When associated with a tendinopathy from age-related degenerative changes within the tendon, impingement may be associated with partial or complete tears of the cuff. Clinically, this condition causes tenderness over the anterior portion of the acromion, and pain which typically occurs on abducting the shoulder between 60° and 120° (the painful arc).

Glenohumeral joint dislocations

The glenohumeral joint is the most frequently dislocated joint in the body. It is most unstable anteroinferiorly, which explains why the vast majority of dislocations are anterior, and occur when the arm is forced backwards when it is in abduction, external rotation and extension. Clinically, a dislocated shoulder loses its normal contour, and the acromion process, rather than the greater tubercle, becomes the most lateral bony structure. The axillary nerve and artery may be injured during dislocation, and this can lead to inability to abduct the shoulder as a result of paralysis of deltoid together with an area of anaesthesia over the distal part of the muscle (sometimes referred to as the ‘badge area’ of skin), as well as ischaemic changes in the limb. Posterior dislocation is rare and typically occurs when violent movements produce marked internal rotation and adduction, e.g. in epileptic seizures or electric shock.
MUSCLES

Pectoralis major

Attachments

Pectoralis major (Fig. 46.19) is a thick, fan-shaped muscle. It arises from the anterior surface of the sternal half of the clavicle; half the breadth of the anterior surface of the sternum down to the level of the sixth or seventh costal cartilage; the first to the seventh costal cartilages (first and seventh often omitted); the sternal end of the sixth rib; and the aponeurosis of external oblique. The clavicular fibres are usually separated from the sternal fibres by a slight cleft. The muscle converges to a flat tendon, approximately 5 cm across, which is attached to the lateral lip of the intertubercular sulcus of the humerus. The tendon is bilaminar. The thicker anterior lamina is formed by fibres from the manubrium, which are joined superficially by clavicular fibres and deeply by fibres from the sternal margin and the second to fifth costal cartilages. Clavicular fibres may be prolonged into the deltoid tendon. The posterior lamina receives fibres from the sixth (and often seventh) costal cartilages, sixth rib, sternum, and aponeurosis of the external oblique. Costal fibres join the lamina without twisting. Fibres from the sternum and aponeurosis curve around the lower border, turning successively behind those above them, which means that this part of the muscle is twisted so that the fibres that are lowest at their medial origin are highest at their insertion on the humerus. The posterior lamina reaches higher on the humerus than the anterior, and gives off an expansion which covers the intertubercular sulcus and blends with the capsular ligament of the shoulder joint. An expansion from the deepest part of the lamina lines the intertubercular sulcus at its linear insertion; from its lower border another expansion descends into the deep fascia of the upper arm.

The rounded lower border of the muscle forms the anterior axillary fold, and becomes conspicuous in abduction against resistance.

Variants

The abdominal slip from the aponeurosis of the external oblique is sometimes absent. The number of costal attachments and the extent to which the clavicular and costal parts are separated vary. Right and left muscles may decussate across the sternum. A superficial vertical slip, or slips, may ascend from the lower costal cartilages and rectus sheath to blend with sternocleidomastoid or to attach to the upper sternum or costal cartilages. This is sternalis (rectus sternalis). The muscle may be partially or completely absent.

Relations

Skin, superficial fascia, platysma, medial and intermediate supraclavicular nerves, breast, and deep fascia are all anterior. The sternum, ribs and costal cartilages, clavipectoral fascia, subclavius, pectoralis minor, serratus anterior, external intercostal muscles and membranes are all posterior. Pectoralis major forms the superficial layer of the anterior axillary wall, and hence lies anterior to the axillary vessels and nerves and the upper parts of biceps and coracobrachialis. Its upper border is separated from deltoid by the infraclavicular fossa, which contains the cephalic vein and deltoid branch of the thoraco-acromial artery. Its lower border forms the anterior axillary fold.
Pectoralis major is separated from latissimus dorsi on the medial axillary wall, but the two muscles converge as they approach the lateral axillary wall: the floor of the intertuberculous sulcus lies between their attachments.

**Vascular supply**

Pectoralis major is supplied by one dominant vascular pedicle from the pectoral branch of the thoraco-acromial axis, supplemented by several smaller secondary segmental vessels from the deltoid and clavicular branches of the thoraco-acromial axis, and perforating branches of the internal thoracic arteries and superior and lateral thoracic arteries.

The presence of a dominant vascular pedicle (together with its musculocutaneous perforators) means that a musculocutaneous flap in this region can be surgically raised solely on the pectoral branch (the pectoralis major musculocutaneous flap). This flap can be used to reconstruct areas of missing tissue following head and neck cancer resections.

**Innervation**

Pectoralis major is supplied through the medial and lateral pectoral nerves. Fibres for the clavicular part are from C5 and 6; those for the sternocostal part are from C6, 7, 8, and T1.

**Action**

The two parts of the muscle can act separately or together. The whole muscle assists adduction and medial rotation of the humerus against resistance. It swings the extended arm forwards and medially, its clavicular part acting with the anterior fibres of deltoid and coracobrachialis: the sternocostal part is relaxed. The opposite movement is usually aided by gravity. When it is resisted, the sternocostal part acts together with latissimus dorsi, teres major and the posterior fibres of deltoid: the clavicular part is relaxed. With the raised arms fixed, e.g. gripping a branch, the same combination of muscles draws the trunk up and forwards. Pectoralis major is active in deep inspiration. Electromyography suggests that the clavicular part acts alone in medial rotation.

**Clinical anatomy: testing**

To test the clavicular head, the abducted arm is flexed against resistance. To test the sternocostal head, the arm is adducted against resistance.

**Poland syndrome**

Poland syndrome is a rare congenital anomaly where there is hypoplasia of the thoracic chest wall muscles and ipsilateral hypoplasia of the arm and hand. It occurs in approximately 1 : 50,000 live births. The major clinical features are that the sternocostal head of pectoralis major and all of pectoralis minor are absent. In addition, there may be hypoplasia of latissimus dorsi, serratus anterior, external oblique, supraspinatus, infraspinatus, deltoid and the intercostal muscles, and hypoplasia of the hemithorax and ribs. There may be ipsilateral breast hypoplasia and absent nipple-areolar-complex (Ch. 55).
Hypoplasia affecting the arm ranges from syndactyly to symbrachydactyly and ectrodactyly. The second, third and fourth fingers are the most affected; the wrist, forearm, upper arm and scapula are variably involved.

The aetiology is unclear. It has been suggested that the condition is caused by disruption of the arterial blood supply to the subclavian vessels during the sixth and seventh week of embryonic life, or by disruption of lateral plate mesoderm 2–4 weeks after fertilization.

**Pectoralis minor**

**Attachments**

Pectoralis minor is a thin, triangular muscle lying posterior (deep) to pectoralis major (Fig. 46.20). It arises from the upper margins and outer surfaces of the third to fifth ribs (frequently second to fourth), near their cartilages, and from the fascia over the adjoining external intercostal muscles. Its fibres ascend laterally under cover of pectoralis major, converging in a flat tendon which is attached to the medial border and upper surface of the coracoid process of the scapula. Part or all of the tendon may cross the coracoid process into the coraco-acromial ligament, or even beyond to the coracohumeral ligament, thereby gaining attachment to the humerus.
Variants

Slips of the muscle are sometimes separated and vary in number and level. In rare cases, one passes from the first rib to the coracoid (pectoralis minimus). The costal attachments can be 2nd to 5th ribs; 3rd to 5th; 2nd to 4th; 3rd to 4th. The muscle can be present or absent when the pectoralis major is absent.

Relations

Pectoralis major, the lateral pectoral nerve and pectoral branches of the thoraco-acromial artery are anterior. The ribs, external intercostals, serratus anterior, the axilla, axillary vessels, lymphatics and brachial plexus are all posterior. The upper border of pectoralis minor is separated from the clavicle by a triangular gap which is filled by the clavipectoral fascia, behind which are the axillary vessels, lymphatics and nerves. The lateral thoracic artery follows the lower border of the muscle. The medial pectoral nerves pierce and partly supply the muscle.

Vascular supply

Pectoralis minor is supplied by pectoral and deltoid branches of the thoraco-acromial and superior and lateral thoracic arteries.

Innervation

Pectoralis minor is innervated by branches of the medial and lateral pectoral nerves, C5, 6, 7, 8 and T1.

Action

Pectoralis minor assists serratus anterior in drawing the scapula forwards around the chest wall. With levator scapulae and the rhomboids it rotates the scapula, depressing the point of the shoulder. Both pectoral muscles are electromyographically quiescent in normal inspiration, but are active in forced inspiration.

Subclavius

Attachments

Subclavius is a small, triangular muscle tucked between the clavicle and the first rib (Fig. 46.20). It arises from the junction of the first rib and its costal cartilage by a thick tendon, prolonged at its inferior margin and anterior to the costoclavicular ligament. It passes upwards and laterally to a groove on the under surface of the middle third of the clavicle, where it is attached by muscular fibres.

Subclavius may be attached to the coracoid process or the upper border of the scapula as well as, or instead of, the clavicle.

Relations
Posteriorly subclavius is separated from the first rib by the subclavian vessels and brachial plexus, and anteriorly it is separated from pectoralis major by the anterior lamina of the clavipectoral fascia.

Vascular supply

Subclavius is supplied by the clavicular branch of the thoraco-acromial artery and the suprascapular artery.

Innervation

Subclavius is supplied by the subclavian branch of the brachial plexus, which contains fibres from C5 and 6.

Action

Subclavius probably pulls the point of the shoulder down and forwards and braces the clavicle against the articular disc of the sternoclavicular joint: however it is inaccessible to palpation, and difficult to investigate by electromyography. It 'protects' the subclavian vessels in fractures of the clavicle, which rarely involve these vessels.

Trapezius

Attachments

Trapezius is a flat, triangular muscle which extends over the back of the neck and upper thorax (Fig. 54.15). The paired trapezius muscles form a diamond shape, from which the name is derived: the lateral angles occur at the shoulder tips, the superior angle at the occipital protuberance and superior nuchal lines, and the inferior angle at the spine of the twelfth thoracic vertebra. On either side, the muscle is attached to the medial third of the superior nuchal line, external occipital protuberance, ligamentum nuchae, and apices of the spinous processes and their supraspinous ligaments from C7 to T12. Superior fibres descend, inferior fibres ascend, and the fibres between them proceed horizontally: all converge laterally on the shoulder. The superior fibres are attached to the posterior border of the lateral third of the clavicle; the middle fibres to the medial acromial margin and superior lip of the crest of the scapular spine; and the inferior fibres pass into an aponeurosis which glides over a smooth triangular surface at the medial end of the scapular spine and is attached to a tubercle at its lateral apex. The occipital attachment is by a fibrous lamina, which is also adherent to the skin. The spinal attachment is by a broad triangular aponeurosis from the sixth cervical to the third thoracic vertebrae, and by short tendinous fibres below this.

Variants

The clavicular attachment of trapezius varies in extent, sometimes reaching mid-clavicle, and occasionally blending with sternocleidomastoid. The vertebral attachment sometimes stops at the eighth thoracic spine. The occipital attachment may be absent. Cervical and dorsal parts are occasionally separate.

Vascular supply

The upper third of trapezius is supplied by a transverse muscular branch which arises from the occipital artery at the level of the mastoid process. It enters the muscle on its
deep surface and gives off several musculocutaneous perforators to the overlying skin.

The middle portion of trapezius, together with an area of overlying skin, is supplied by the superficial cervical artery or by a superficial branch of the transverse cervical artery, via musculocutaneous perforators.

The lower third of trapezius is supplied by a muscular branch from the dorsal scapular artery, passing medial to the medial border of the scapula. It reaches the deep surface of the muscle either by piercing the rhomboids or by passing between rhomboid major and minor at the level of the base of the spine of the scapula. It anastomoses with the medial and lateral perforating branches of the posterior intercostal arteries.

The presence of these three discrete vascular pedicles means that musculocutaneous flaps can be surgically raised based on these individual arteries and their accompanying venae comitantes. These flaps can be used for reconstructing areas in the posterior head and neck.

Innervation

Trapezius is innervated by the spinal part of the accessory nerve. Sensory (proprioceptive) branches are derived from the ventral rami of C3 and C4.

Action

Trapezius cooperates with other muscles in steadying the scapula, controlling it during movements of the arm, and maintaining the level and poise of the shoulder. Electromyographic activity is minimal in the unloaded arm, and heavy loads can be suspended with a small contribution from the upper part. Acting with levator scapulae, the upper fibres elevate the scapula and with it the point of the shoulder; acting with serratus anterior, trapezius rotates the scapula forward (upwards) so that the arm can be raised above the head; and acting with the rhomboids, it retracts the scapula, bracing back the shoulder. With the shoulder fixed, trapezius may bend the head and neck backwards and laterally. Trapezius, levator scapulae, rhomboids and serratus anterior combine in producing a variety of scapular rotations (p. 803).

Clinical anatomy: testing

Trapezius is palpated while the shoulder is shrugged against resistance.

Deltoid

Attachments

Deltoid is a thick, curved triangle of muscle. It arises from the anterior border and superior surface of the lateral third of the clavicle, the lateral margin and superior surface of the acromion, and the lower edge of the crest of the scapular spine (other than its smooth medial triangular surface) (Fig. 46.19). The fibres converge inferiorly to a short, substantial tendon which is attached to the deltoid tubercle on the lateral aspect of the midshaft of the humerus. Anterior and posterior fibres converge directly to this tendon. The intermediate part is multipennate: four intramuscular septa descend from the acromion to interdigitate with three septa ascending from the deltoid tubercle. The septa are connected by short muscle fibres, which provide powerful
traction. The fasciculi are large, producing a coarse longitudinal striation. The muscle surrounds the glenohumeral articulation on all sides except inferomedially, lending the shoulder its rounded profile. In contraction its borders are easily seen and felt. The tendon gives off an expansion into the brachial deep fascia which may reach the forearm.

**Variants**

Deltoid may fuse with pectoralis major or may receive additional slips from trapezius, the infraspinous fascia or the lateral scapular border.

**Relations**

The skin, superficial and deep fasciae, platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves are all superficial. The coracoid process, coraco-acromial ligament, subacromial bursa, tendons of pectoralis minor, coracobrachialis, both heads of biceps, pectoralis major, subscapularis, supraspinatus, infraspinatus, teres minor, long and lateral heads of triceps, the circumflex humeral vessels, axillary nerve, and the surgical neck and upper shaft of the humerus, including both tubercles, all lie deep to deltoid. The anterior border of the muscle is separated proximally from pectoralis major by the infraclavicular fossa, which contains the cephalic vein and deltoid branches of the thoraco-acromial artery. Distally, the muscles are in contact, and their tendons are usually united. The posterior border overlies infraspinatus and triceps.

**Vascular supply**

Deltoid is supplied by acromial and deltoid branches of the thoraco-acromial artery; the anterior and posterior circumflex humeral arteries; subscapular artery; and the deltoid branch of profunda brachii.

**Innervation**

Deltoid is innervated by the axillary nerve, C5 and 6.

**Action**

Different parts of the muscle can act independently as well as together. Anterior fibres assist pectoralis major in drawing the arm forwards and rotating it medially. Posterior fibres act with latissimus dorsi and teres major in drawing the arm backwards and rotating it laterally. The multipennate acromial part of deltoid is a strong abductor: aided by supraspinatus it abducts the arm until the joint capsule is tense below. Movement takes place in the plane of the body of the scapula, which is the only way that scapular rotation can be fully effective in raising the arm above the head. In true abduction (Fig. 46.19), acromial fibres contract strongly, while clavicular and posterior fibres prevent departure from the plane of motion. In the early stages of abduction, traction by the deltoid is upward, but the humeral head is prevented from translating upward by the synergistic downward pull of subscapularis, infraspinatus and teres minor. Electromyography suggests that deltoid contributes little to medial or lateral rotation but confirms that it takes part in most other shoulder movements. It may also aid supraspinatus in resisting the downward drag of a loaded arm. A common action of the deltoid is arm-swinging while walking.
Deltoid can be seen and felt to contract when the arm is abducted against resistance.

*Levator scapulae*

**Attachments**

Levator scapulae is a slender muscle attached by tendinous slips to the transverse processes of the atlas and axis, and to the posterior tubercles of the transverse processes of the third and fourth cervical vertebrae (Fig. 28.6, see below Fig. 46.21). It descends diagonally to approach the medial scapular border between its superior angle and the triangular smooth surface at the medial end of the scapular spine.

*Fig. 46.21* Rhomboid muscles.
Variants

Levator scapulae varies considerably in its vertebral attachments and the extent to which it separates into slips. There may be accessory attachments to the mastoid process, occipital bone, first or second rib, scaleni, trapezius, and serratus muscles.

Vascular supply

Levator scapulae receives its arterial supply mainly from the transverse cervical and ascending cervical arteries. The vertebral extremity of the muscle is supplied by branches from the vertebral artery.

Innervation

Levator scapulae is innervated directly by branches of the third and fourth cervical spinal nerves, and from the fifth cervical nerve via the dorsal scapular nerve.

Action

The levator scapulae and the rhomboids assist other scapular muscles in controlling the position and movement of the scapula. Acting with trapezius, rhomboids retract the scapula, bracing back the shoulder; with levator scapulae and pectoralis minor they rotate the scapula, depressing the point of the shoulder. With the cervical vertebral column fixed, levator scapulae acts with trapezius to elevate the scapula or to sustain a weight carried on the shoulder; with the shoulder fixed, the muscle inclines the neck to the same side.

Rhomboid major

Attachments

Rhomboid major is a quadrilateral sheet of muscle which arises by tendinous fibres from the spines and supraspinous ligaments of the second to fifth thoracic vertebrae, and descends laterally to the medial border of the scapula between the root of the spine and the inferior angle (Fig. 46.21). Most of its fibres usually end in a tendinous band between these two points, joined to the medial border by a thin membrane. Occasionally this is incomplete, in which case some muscular fibres are attached directly into the scapula. The attachments of rhomboid major – and also those of rhomboid minor, levator scapulae and serratus anterior – can be more extensive, with ‘folds’ or extensions passing to both dorsal and costal aspects of the scapula adjacent to its medial margin.

Vascular supply, innervation, action and clinical anatomy: testing

All are described with rhomboid minor.

Rhomboid minor

Attachments

Rhomboid minor is a small, cylindrical muscle. It runs from the lower ligamentum nuchae and the spines of the seventh cervical and first thoracic vertebrae to the base of a smooth triangular surface at the medial end of the spine of the scapula, where dorsal and ventral layers enclose the inferior border of levator scapulae (Fig. 46.21).
The dorsal layer of rhomboid minor is attached to the rim of the triangular surface, dorsolateral to and below levator scapulae. The ventral layer is strong and wide, extending 2–3 cm medial to and below levator scapulae; here the fasciae of rhomboid minor and serratus anterior are tightly fused. Rhomboid minor is usually separate from rhomboid major, but the muscles overlap and are occasionally united.

Variants

There is some variability in the vertebral and scapular attachments of rhomboids major and minor. A slip of muscle may extend from the upper border of rhomboid minor to reach the occipital bone (rhomboid occipitalis).

Vascular supply of the rhomboids

Rhomboids major and minor are supplied by the dorsal scapular artery or deep branch of the transverse cervical artery and by dorsal perforating branches from the upper five or six posterior intercostal arteries.

Innervation of the rhomboids

Rhomboids major and minor are innervated by a branch of the dorsal scapular nerve, C4, 5.

Action of the rhomboids

Both rhomboid major and minor retract the medial border of the scapula superiorly and medially. They are used in squaring the shoulders.

Clinical anatomy: testing of the rhomboids

Rhomboids major and minor can be palpated deep to trapezius on bracing the shoulder back against resistance.

Latissimus dorsi

Attachments

Latissimus dorsi is a large, flat, triangular muscle that sweeps over the lumbar region and lower thorax and converges to a narrow tendon (Fig. 46.22, Fig. 54.15). It arises by tendinous fibres from the spines of the lower six thoracic vertebrae anterior to trapezius; from the posterior layer of thoracolumbar fascia, by which it is attached to the spines and supraspinous ligaments of the lumbar and sacral vertebrae; and from the posterior part of the iliac crest. It also springs by muscular fibres from the posterior part (outer lip) of the iliac crest lateral to erector spinae, and by fleshy slips from the three or four lower ribs, interdigitating with external oblique (Fig. 61.9). From this extensive attachment, fibres pass laterally with different degrees of obliquity (the upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical) to form a sheet approximately 12 or 13 mm thick that overlaps the inferior scapular angle. The muscle curves around the inferolateral border of teres major to gain its anterior surface. Here it ends as a flattened tendon, approximately 7 cm long, in front of the tendon of teres major. It is attached to the floor of the intertubercular sulcus of the humerus, with an expansion to the deep fascia. The attachment extends higher on the humerus than that of teres major. As the muscle curves round teres major, the
fasciculi rotate around each other, so that fibres that originate lowest at the midline insert highest on the humerus, and fibres that originate highest at the midline insert lowest on the humerus. A bursa sometimes occurs between the muscle and the inferior scapular angle. The tendons of latissimus dorsi and teres major are united at their lower borders: they are separated by a bursa near their humeral attachments.

![Fig. 46.22 Deep muscles of the left shoulder girdle. A, Anterior aspect after removal of several superficial muscles. B, Posterior aspect. (From Sobotta 2006.)](image)

Latissimus dorsi and teres major together form the posterior axillary fold. When the arm is adducted against resistance, this fold is accentuated, and the whole inferolateral border of latissimus dorsi can then be traced to its attachment to the iliac crest.
The lower, lateral margin of the muscle is usually separated from the posterior border of external oblique by the lumbar triangle; the base of this small triangle is the iliac crest and its floor the internal oblique. It should not be confused with the triangle of auscultation, which is medial to the scapula, and is bounded above by the trapezius, below by latissimus dorsi and laterally by the medial border of the scapula; part of rhomboid major is exposed in the triangle. If the scapulæ are drawn forwards, by folding the arms across the chest, and the trunk is bent forwards, parts of the sixth and seventh ribs and the interspace between them (overlying the apex of the lower pulmonary lobe) become subcutaneous.

Variants

Latissimus dorsi commonly receives some additional fibres from the scapula as it crosses the inferior scapular angle. A muscular axillary arch, 7–10 cm in length and 5–15 mm in breadth, may sometimes be present: it crosses from the edge of latissimus dorsi, midway in the posterior fold, over the front of the axillary vessels and nerves to join the tendons of pectoralis major, coracobrachialis or the fascia over the biceps. The vertebral and costal attachments of latissimus dorsi may be reduced or, in rare cases, increased. A fibrous slip usually passes from the tendon, near its humeral insertion, to the long head of triceps.

Vascular supply

Latissimus dorsi is supplied by a single dominant vascular pedicle, the thoracodorsal artery, itself a continuation of the subscapular artery (p. 817). The thoracodorsal artery (and its accompanying venae comitantes) enters the muscle at a single neurovascular hilum on its costal surface, 6–12 cm from the subscapular artery and 1–4 cm medial to the lateral border of the muscle. The artery gives off one to three large branches to serratus anterior before dividing at, or even before, the hilum to supply latissimus dorsi itself. The basic pattern of branching is a bifurcation into lateral and medial branches. The larger lateral branch follows a course parallel to, and 1–4 cm from, the upper border of the muscle; the smaller branch diverges at an angle of 45° and travels medially. In a small number of cases the artery trifurcates: this usually yields a small recurrent branch which returns to supply the proximal part of the muscle, but in some cases it provides a third major branch which supplies the distal part of the muscle. Occasionally the lateral branch gives off a further collateral to serratus anterior. The major branches give off 5–9 longitudinal branches which travel distally, parallel with the muscle fibres. Musculocutaneous perforators arising from these vessels supply the overlying skin.

In addition to the dominant vascular pedicle, latissimus dorsi is supplied inferiorly by several smaller secondary segmental vascular pedicles. These are dorsal perforating arteries derived from the 9th, 10th and 11th posterior intercostal and 1st, 2nd and 3rd lumbar arteries, and they all enter the muscle on its deep surface. They anastomose within the muscle with branches of the thoracodorsal artery.

The blood supply of latissimus dorsi is particularly important because of its applications in plastic and reconstructive surgery. The presence of the dominant vascular pedicle provides the anatomical basis for raising the muscle either alone, or together with an overlying paddle of skin in the form of a musculocutaneous flap based solely on the thoracodorsal artery and its accompanying venae comitantes. These flaps can be used in a pedicle fashion, e.g. in reconstructing a breast following
a mastectomy, or used as free tissue transfer to cover large areas of tissue loss anywhere in the body.

Innervation

Latissimus dorsi is supplied by the thoracodorsal nerve, from the posterior cord of the brachial plexus, C6, 7 and 8. This nerve runs in the neurovascular pedicle and divides approximately 1.3 cm proximal to the point of bifurcation or trifurcation of the thoracodorsal artery. The pattern of branching follows that of the artery closely, and the neural and vascular branches travel together.

Action

Latissimus dorsi is active in adduction, extension and especially in medial rotation of the humerus. Humeral adduction and extension are most powerful when the initial position of the arm is one of partial abduction, flexion or a combination of the two. With the sternocostal part of pectoralis major and teres major it adducts the raised arm against resistance. It assists backward swinging of the arm, as in walking and many athletic pursuits. When the arms are raised above the head, as in climbing, it pulls the trunk upwards and forwards. It takes part in all violent expiratory efforts, such as coughing or sneezing: this is readily confirmed by palpation. Electromyography suggests that it aids deep inspiration, but it is also active towards the end of forcible expiration, e.g. when blowing a sustained note on a musical instrument. When the arm is elevated, the stretched fibres of latissimus dorsi press on the inferior scapular angle, keeping it in contact with the chest wall. Despite this range of actions, surgical transposition of the muscle does not produce any serious restriction of normal activity.

Clinical anatomy: testing

Latissimus dorsi is palpated when the abducted arm is adducted against resistance and can be felt to contract during coughing.

Serratus anterior

Attachments

Serratus anterior is a large muscular sheet which curves around the thorax. It arises from an extensive costal attachment and inserts on the scapula (Fig. 46.19, Fig. 46.20). Fleshy digitations spring anteriorly from the outer surfaces and superior borders of the upper eight, nine or even ten ribs, and from fasciae which cover the intervening intercostals. They lie on a long, slightly curved, line which passes inferolaterally across the thorax. The first digitations spring from the first and second ribs and intercostal fascia, the others from a single rib, and the lower four interdigitate with the upper five slips of external oblique. The muscle follows the contour of the chest wall closely. It passes ventral to the scapula and reaches the medial border of the scapula in the following way. The first digitation encloses, and is attached to, a triangular area of both the costal and dorsal surfaces of the superior scapular angle. The next two or three digitations form a triangular sheet which is attached to the costal surface along almost its entire medial border. The lower four or five digitations converge to be attached by musculotendinous fibres to a triangular impression on the costal surface of the inferior angle: they enclose the inferior angle and are also attached to a smaller triangular part of its dorsal surface near its tip.
Variants

Digitations may be absent, particularly the first and eighth, and sometimes also the intermediate part. Serratus anterior may be partly fused with levator scapulae, adjacent external intercostals or external oblique.

Vascular supply

Serratus anterior is supplied by superior and lateral thoracic arteries, and branches from the thoracodorsal artery before (occasionally after) it divides in latissimus dorsi.

Innervation

Serratus anterior is innervated by the long thoracic nerve, C5, 6 and 7, which descends on the external surface of the muscle.

Action

With pectoralis minor, serratus anterior protracts (draws forward) the scapula, as a prime mover in all reaching and pushing movements. The upper part, with levator scapulae and upper fibres of trapezius, suspends the scapula, but slight activity is sufficient to support the unloaded arm. The heavier insertion lower down pulls the inferior scapular angle forwards around the thorax, assisting trapezius in upward rotation of the bone, an action that is essential to raising the arm above the head. In the initial stages of abduction, serratus anterior helps other muscles to fix the scapula, so that deltoid acts effectively on the humerus, and not the scapula. While deltoid is raising the arm to a right angle with the scapula, serratus anterior and trapezius are simultaneously rotating the scapula: the combination allows the arm to be raised to the vertical. To effect this upward rotation of the scapula, forward pull on the inferior angle by the lower digitations of serratus anterior is coupled with an upward and medial pull on the lateral end of the clavicle and acromion by the upper fibres of trapezius, and a downward pull on the base of the scapular spine by the lower fibres of trapezius. Conversely, slow downward scapular rotation assisted by gravity is achieved by controlled lengthening of these muscles. More powerful downward rotation requires balanced contraction of the upper fibres of serratus anterior, levator scapulae, rhomboids, pectoralis minor and the middle part of trapezius. When weights are carried in front of the body, serratus anterior prevents backward rotation of the scapula. Electromyography shows that serratus anterior is not active in normal human respiration. This may not apply to laboured respiration, e.g. when asthmatics and athletes may be observed to fix the scapula by grasping a rail or other support.

Clinical anatomy: testing

The muscular digitations of serratus anterior can be seen and felt when the outstretched hand pushes against resistance.

When serratus anterior is paralysed, the medial border of the scapula, and especially its lower angle, stand out prominently. The arm cannot be raised fully. Pushing is ineffective, indeed attempts to do so produce further projection, known as ‘winging’ of the scapula.

Supraspinatus
Attachments

Supraspinatus arises from the medial two-thirds of the supraspinous fossa and from the supraspinous fascia (Fig. 46.22). The fibres converge, under the acromion, into a tendon which crosses above the shoulder joint and is attached to the highest facet of the greater tubercle of the humerus. The tendon blends into the articular capsule and may give a slip to the tendon of pectoralis major. Fibrocartilage has been described at the tendinous insertion, as in other tendons attached to epiphysial bone.

Vascular supply

Supraspinatus is supplied by the suprascapular and dorsal scapular arteries.

Innervation

Supraspinatus is innervated by the suprascapular nerve, C5 and 6.

Action

The conventional view is that supraspinatus initiates abduction of the shoulder and assists deltoid in abduction thereafter. However, there is evidence that both supraspinatus and deltoid are involved throughout the range of abduction, including initiation of the movement. As part of the rotator cuff, supraspinatus helps to stabilize the head of the humerus in the glenoid fossa during movements of the glenohumeral joint. With the arm dependent, even when moderately loaded, supraspinatus and tension in the upper capsule prevent downward displacement of the humerus.

Clinical anatomy: testing

Supraspinatus can be palpated deep to trapezius when the arm is abducted at the shoulder joint against resistance.

The tendon of supraspinatus is separated from the coraco-acromial ligament, acromion and deltoid by the large subacromial bursa; when this is inflamed, abduction of the shoulder joint is painful. The tendon is the most frequently torn element of the musculotendinous cuff around the shoulder joint.

Infraspinatus

Attachments

Infraspinatus is a thick triangular muscle which occupies most of the infraspinous fossa (Fig. 46.22). It arises by muscular fibres from the medial two-thirds of the fossa, by tendinous fibres from ridges on its surface and from the deep surface of the infraspinous fascia, which separates it from teres major and minor. Its fibres converge to a tendon which glides under the lateral border of the spine of the scapula, and then passes across the posterior aspect of the capsule of the shoulder joint to be attached to the middle facet on the greater tubercle of the humerus. The tendon is sometimes separated from the capsule by a bursa, which may communicate with the joint cavity. Infraspinatus is sometimes fused with teres minor.

Vascular supply

Infraspinatus is supplied by the suprascapular and circumflex scapular arteries.
Innervation

Infraspinatus is innervated by the suprascapular nerve, C5 and 6.

Action

Infraspinatus is a lateral rotator of the humerus. Together with supraspinatus, subscapularis and teres minor, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements (p. 806).

Subscapularis

Attachments

Subscapularis is a bulky, triangular muscle which fills the subscapular fossa (Fig. 46.20). In its medial two-thirds, the fibres are attached to the periosteum of the costal surface of the scapula. Other fibres arise from tendinous intramuscular septa, which are attached to ridges on the bone, and from the aponeurosis which covers the muscle and separates it from teres major and the long head of triceps. The fibres converge laterally into a broad tendon which is attached to the lesser tubercle of the humerus and the front of the articular capsule. The tendon is separated from the neck of the scapula by the large subscapular bursa, which communicates with the shoulder joint.

Variation is unusual. A separate slip may pass from the medial border of the scapula to the glenohumeral capsule or to the periosteum medial to the intertuberculous sulcus of the humerus.

Relations

Subscapularis forms much of the posterior axillary wall. Its anterior surface is apposed inferomedially to serratus anterior, and superolaterally to coracobrachialis and biceps, the axillary vessels, brachial plexus and subscapular vessels and nerves. Its posterior surface is attached to the scapula and glenohumeral capsule. Its lower border contacts teres major and latissimus dorsi.

Vascular supply

Subscapularis is supplied by small branches from the suprascapular, axillary and subscapular arteries.

Innervation

Subscapularis is innervated by the upper and lower subscapular nerves, C5, 6.

Action

Subscapularis is a medial rotator of the humerus. Together with supraspinatus, infraspinatus and teres minor, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements (p. 806).

Teres major
Attachments

Teres major is a thick, flat muscle which arises from the oval area on the dorsal surface of the inferior scapular angle, and from the fibrous septa interposed between the muscle and teres minor and infraspinatus (Fig. 46.22). Its fibres ascend laterally and end in a flat tendon, approximately 5 cm long, which is attached to the medial lip of the intertubercular sulcus of the humerus. The tendon lies behind that of latissimus dorsi, from which it is separated by a bursa; the tendons are united along their lower borders for a short distance.

Variants

Teres major may be fused with the scapular part of latissimus dorsi, and it may send a slip to join the long head of triceps or the brachial fascia.

Vascular supply

Teres major is supplied by the thoracodorsal branch of the subscapular artery on its way to latissimus dorsi and by the posterior circumflex humeral artery.

Innervation

Teres major is innervated by the lower subscapular nerve, C5, 6 and 7.

Action

Despite its name, teres major has a nerve supply and action that is distinct from teres minor. Teres major draws the humerus backwards and rotates it medially. Electromyographic studies are equivocal about its major role in movement, but its involvement as a contributor to static posture and arm-swinging is not contested.

Clinical anatomy: testing

Teres major can be palpated posterior to the posterior axillary fold during adduction of the humerus against resistance.

Teres minor

Attachments

Teres minor is a narrow elongated muscle which arises from the upper two-thirds of a flattened strip on the dorsal surface of the scapula adjoining its lateral border, and from two aponeurotic laminae which separate it from infraspinatus and teres major (Fig. 46.22). It runs upwards and laterally. The upper fibres end in a tendon attached to the lowest facet on the greater tubercle of the humerus. The lower fibres are attached directly into the humerus distal to this facet and above the origin of the lateral head of triceps. The tendon passes across, and blends with, the lower posterior surface of the capsule of the shoulder joint.

Teres minor may be fused with infraspinatus.

Vascular supply

Teres minor is supplied by the circumflex scapular artery, which pierces the origin of
the muscle as it turns upward in the infraspinous fossa, and by the posterior circumflex humeral artery.

Innervation

Teres minor is innervated by the axillary nerve, C5 and 6.

Action

Teres minor acts as a lateral rotator and weak adductor of the humerus. Together with supraspinatus, infraspinatus and subscapularis, it helps stabilize the head of the humerus in the glenoid fossa during shoulder movements (p. 803).

The quadrangular and triangular spaces

Anteriorly, the quadrangular space is bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally. Posteriorly, the quadrangular space is bounded above by teres minor. The axillary nerve and the posterior circumflex artery and vein pass through the space (Fig. 46.22).

There are two triangular spaces (Fig. 46.22). The upper triangular space is bounded above by subscapularis anteriorly, teres minor posteriorly, teres major below, and the long head of triceps laterally. The circumflex scapular artery passes through this space. The lower triangular space (triangular interval) is bounded above by subscapularis anteriorly and teres major posteriorly; the long head of triceps medially and the humerus laterally. The radial nerve and the profunda brachii vessels pass through this space.
AXILLA

BOUNDARIES

The axilla is a pyramidal region between the upper thoracic wall and the arm (Fig. 46.23, Fig. 46.24). Its blunt apex continues into the root of the neck (cervico-axillary canal) between the external border of the first rib, superior border of the scapula, posterior surface of the clavicle and the medial aspect of the coracoid process. Its base, which is virtual, can be imagined as facing downwards: it is broad at the chest and narrow at the arm, and corresponds to the skin and a thick layer of axillary fascia between the inferior borders of pectoralis major anteriorly and latissimus dorsi posteriorly. It is convex upwards, conforming to the concavity of the armpit.
Fig. 46.23 Transverse section through left shoulder joint and axilla, viewed from below. Compare with Fig. 46.17A.
The anterior wall is formed by pectorales major and minor, the former covering the whole wall, the latter its intermediate part. The interval between the upper border of pectoralis minor and clavicle is occupied by the clavipectoral fascia. The posterior wall is formed by subscapularis above, and teres major and latissimus dorsi below. The medial ‘wall’ is convex laterally
and is composed of the first four ribs and their associated intercostal muscles, together with the upper part of serratus anterior. The anterior and posterior walls converge laterally: the ‘wall’ is narrow and consists of the humeral intertubercular sulcus. The lateral angle lodges coracobrachialis and biceps.
The axilla contains the axillary vessels, the infraclavicular part of the brachial plexus and its branches, lateral branches of some intercostal nerves, many lymph nodes and vessels, loose adipose areolar tissue and, in many instances, the 'axillary tail' of the breast. The axillary vessels and brachial plexus run from the apex to the base along the lateral wall, nearer to the anterior wall: the axillary vein is anteromedial to the artery. The obliquity of the upper ribs means that the neurovascular bundle, after it emerges from behind the clavicle, crosses the first intercostal space: its relations are therefore different at upper and lower levels. Thoracic branches of the axillary artery are in contact with the pectoral muscles; the lateral thoracic artery reaches the thoracic wall along the lateral margin of pectoralis minor. Subscapular vessels descend on the posterior wall at the lower margin of subscapularis. The subscapular and thoracodorsal nerves cross the anterior surface of latissimus dorsi at different inclinations. Circumflex scapular vessels wind round the lateral border of the scapula; posterior circumflex humeral vessels and the axillary nerve curve back and laterally around the surgical neck of the humerus.

No large vessel lies on the medial 'wall', which is crossed proximally only by small branches of the superior thoracic artery. The long thoracic nerve descends on serratus anterior and the intercostobrachial nerve perforates the upper anterior part of this wall, crossing the axilla to its lateral 'wall'.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIES

Suprascapular artery

The suprascapular artery usually arises from the thyrocervical trunk of the subclavian artery, although it may arise from the third part of the subclavian artery (Fig. 28.7). It first descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid, then crosses anterior to the subclavian artery and brachial plexus, posterior and parallel with the clavicle and subclavius and the inferior belly of omohyoid, to reach the superior border of the scapula. Here it passes above (sometimes under) the superior transverse ligament, separating it from the suprascapular nerve, and enters the supraspinous fossa (Fig. 46.25), where it lies on the bone, and supplies supraspinatus. It descends behind the scapular neck, and passes through the spinoglenoid notch deep to the inferior transverse ligament to gain the deep surface of infraspinatus, where it anastomoses with the circumflex scapular and deep branch of the transverse cervical artery. Its muscular branches supply sternocleidomastoid, subclavius and infraspinatus. It also gives off a suprasternal branch which crosses the sternal end of the clavicle to supply the skin of the upper thorax, and an acromial branch which pierces trapezius to supply the skin over the shoulder. This last branch anastomoses with the thoraco-acromial and posterior circumflex humeral arteries.
As the suprascapular artery passes over the superior transverse ligament, it gives off a branch which enters the subscapular fossa beneath subscapularis and anastomoses with the subscapular artery and the deep branch of the transverse cervical artery. It also supplies the acromioclavicular and glenohumeral joints, the clavicle and the scapula.

**Dorsal scapular artery**

In the majority of cases, the dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It passes laterally through the trunks of the brachial plexus in front of scalenus medius and then deep to levator scapulae to reach...
the superior scapular angle. Here it descends with the dorsal scapular nerve under
the rhomboids along the medial border of the scapula to the inferior angle (Fig. 46.25).
It supplies the rhomboids, latissimus dorsi and the inferior portion of trapezius. It
supplies the skin over the inferomedial aspect of trapezius via musculocutaneous
perforators. It anastomoses with the suprascapular and subscapular and with
posterior branches of some posterior intercostal arteries. It sends a small branch to
scalenus anterior: sometimes this arises directly from the subclavian artery.

Variants

About a third of the superficial cervical and dorsal scapular arteries arise in common
from the thyrocervical trunk as a transverse cervical artery, together with a superficial
and a deep branch (superficial cervical and dorsal scapular arteries respectively). In
this case the dorsal scapular artery arises near the superior border of the scapula: it
passes laterally, anterior to the brachial plexus and then posterior to levator scapulae
(Fig. 46.26).

Supraclavicular artery

This small vessel arises from either the transverse cervical or superficial cervical
artery. It pierces the deep fascia just superior to the clavicle and anterior to trapezius
and supplies an area of skin over the lateral end of the clavicle.

Axillary artery

The axillary artery, a continuation of the subclavian artery, begins at the outer border
of the first rib, and ends nominally at the inferior border of teres major where it
becomes the brachial artery. Its direction varies with the position of the limb: it is
almost straight when the arm is raised at right angles, concave upwards when the arm
is elevated above this, and convex upwards and laterally when the arm is by the side. At first deep, it subsequently becomes superficial, when it is covered only by the skin and fasciae. Pectoralis minor crosses it and so divides it into three parts which are proximal, posterior and distal to the muscle.

Relations of the first part

The skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of pectoralis major and the clavpectoral fascia, lateral pectoral nerve and the loop of communication between the lateral and medial pectoral nerves, and the thoraco-acromial and cephalic veins are all anterior. The first intercostal space and external intercostal, first and second digitations of serratus anterior, long thoracic and medial pectoral nerves and the medial cord of the brachial plexus are all posterior. The posterior cord of the brachial plexus is lateral and the axillary vein is anteromedial. The first part is enclosed with the axillary vein and brachial plexus in a fibrous axillary sheath, which is continuous with the prevertebral layer of the deep cervical fascia.

Relations of the second part

The skin, superficial and deep fascia, and pectorales major and minor are all anterior. The posterior cord of the brachial plexus and the areolar tissue between it and subscapularis are posterior. The axillary vein is medial, separated from the artery by the medial cord of the brachial plexus and the medial pectoral nerve. The lateral cord of the brachial plexus is lateral, separating the artery from coracobrachialis. The cords of the brachial plexus thus surround the second part on three sides, with the dispositions implied by their names, and separate it from the vein and adjacent muscles.

Relations of the third part

Pectoralis major, and, distal to the muscle, skin and fasciae, are anterior. The lower part of subscapularis and the tendons of latissimus dorsi and teres major are posterior. Coracobrachialis is lateral and the axillary vein is medial. Branches of the brachial plexus are arranged as follows: laterally, the lateral root and then trunk of the median nerve and, for a short distance, the musculocutaneous nerve; medially, the medial cutaneous nerve of the forearm between the axillary artery and vein anteriorly, and the ulnar nerve between these vessels posteriorly; anteriorly, the medial root of the median nerve; posteriorly, the radial and axillary nerves, the latter only to the distal border of subscapularis.

Branches

The branches of the axillary artery are superior thoracic, thoracoacromial, lateral thoracic, subscapular, anterior and posterior circumflex humeral.

Superior thoracic artery

The superior thoracic artery is a small vessel which arises from the first part of the axillary artery near the lower border of subclavius: it sometimes arises from the thoraco-acromial artery (Fig. 46.24). It runs anteromedially above the medial border of pectoralis minor, then passes between it and pectoralis major to gain the thoracic wall.
It supplies these muscles and the thoracic wall, and anastomoses with the internal thoracic and upper intercostal arteries.

**Thoraco-acromial (acromio-thoracic) artery**

The thoraco-acromial artery is a short branch which arises from the second part of the axillary artery (Fig. 28.7, Fig. 46.19). It is at first overlapped by pectoralis minor; skirting its medial border, next pierces the clavipectoral fascia and divides into pectoral, acromial, clavicular and deltoid branches, which supply pectoralis major and minor, an area of skin over the clavipectoral fascia and the anterior portion of deltoid.

**Pectoral branch**

The pectoral branch is the largest branch. It descends between the pectoral muscles, gives a branch to pectoralis minor, and then continues on the deep surface of pectoralis major. It enters the muscle and anastomoses with the intercostal branches of the internal thoracic and lateral thoracic arteries. It gives off perforating branches to the breast, and musculocutaneous perforators to the skin over pectoralis major.

**Acromial branch**

The acromial branch crosses the coracoid process under deltoid, which it supplies, pierces the muscle and ends on the acromion. It anastomoses with branches of the suprascapular artery, the deltoid branch of the thoraco-acromial artery and the posterior circumflex humeral arteries.

**Clavicular branch**

The clavicular branch ascends medially between the clavicular part of pectoralis major and the clavipectoral fascia. It supplies the sternoclavicular joint and subclavius.

**Deltoid branch**

The deltoid branch often arises with the acromial branch. It crosses pectoralis minor to accompany the cephalic vein between pectoralis major and deltoid, and supplies both muscles.

**Lateral thoracic artery**

The lateral thoracic artery arises from the second part of the axillary artery. Following the lateral border of pectoralis minor, it passes to the deep surface of pectoralis major as far distally as the fifth intercostal space. It supplies serratus anterior and the pectoral muscles, the axillary lymph nodes and subscapularis. It anastomoses with the internal thoracic, subscapular, and intercostal arteries and with the pectoral branch of the thoraco-acromial artery. In females it is large and has lateral mammary branches, which curve round the lateral border of pectoralis major to the breast. In both males and females, it gives off cutaneous branches which pass around the lateral border of pectoralis major to supply the skin in this region.

**Subscapular artery**

The subscapular artery is the largest branch of the axillary artery (Fig. 46.24, Fig. 46.25). It usually arises from the third part of the axillary artery at the distal (inferior)
border of subscapularis, which it follows to the inferior scapular angle, where it anastomoses with the lateral thoracic and intercostal arteries and the deep branch of the transverse cervical artery. It supplies adjacent muscles and the thoracic wall. It is accompanied distally by the nerve to latissimus dorsi. Approximately 4 cm from its origin the subscapular artery divides into the circumflex scapular and thoracodorsal arteries.

**Circumflex scapular artery**

The circumflex scapular artery, the larger of the two terminal branches of the subscapular artery, curves backwards around the lateral border of the scapula, traversing a triangular space between subscapularis above and teres major below and the long head of the triceps laterally. It enters the infraspinous fossa under teres minor and then divides. One branch (infrascapular) enters the subscapular fossa deep to subscapularis, and anastomoses with the suprascapular and dorsal scapular arteries (or deep branch of the transverse cervical artery). The other branch continues along the lateral border of the scapula between teres major and minor and, dorsal to the inferior angle, anastomoses with the dorsal scapular artery. Small branches supply the posterior part of deltoid and the long head of triceps, and anastomose with an ascending branch of the profunda brachii artery.

Two significant cutaneous branches arise from the circumflex scapular artery as it emerges through the upper triangular space. The superior, or horizontal, branch is a direct cutaneous artery which passes medially at the level of the deep fascia parallel with the spine of the scapula: it supplies a band of skin overlying the spine of the scapula. The lower branch (parascapular branch) is also a direct cutaneous vessel which passes in an inferomedial direction, again at the level of the deep fascia, and supplies an area of skin overlying the lateral border of the scapula. Both these cutaneous vessels provide the anatomical basis of skin flaps which can be surgically raised in this region (scapular flap based on the horizontal branch and parascapular flap based on the lower, parascapular branch) to reconstruct areas of missing tissue elsewhere in the body.

**Thoracodorsal artery**

The other terminal branch of the subscapular artery, the thoracodorsal artery, follows the lateral margin of the scapula, posterior to the lateral thoracic artery, between latissimus dorsi and serratus anterior. Before entering the deep surface of latissimus dorsi, it supplies teres major and the intercostals and sends one or two branches to serratus anterior. It enters latissimus dorsi muscle with the thoracodorsal nerve: this constitutes the principle neurovascular pedicle to the muscle. It provides numerous musculocutaneous perforators which supply the skin over the superior part of latissimus dorsi. The intramuscular portion of the artery anastomoses with intercostal arteries and lumbar perforating arteries.

**Anterior circumflex humeral artery**

The anterior circumflex humeral artery arises from the lateral side of the axillary artery at the distal border of subscapularis. It runs horizontally behind coracobrachialis and the short head of biceps, anterior to the surgical neck of the humerus. Reaching the intertubercular sulcus, it sends an ascending branch to supply the humeral head and shoulder joint. It continues laterally under the long head of biceps and deltoid, and
anastomoses with the posterior circumflex humeral artery.

**Posterior circumflex humeral artery**

The posterior circumflex humeral artery is larger than the anterior (Fig. 46.25, Fig. 46.27). It branches from the third part of the axillary artery at the distal border of subscapularis and runs backwards with the axillary nerve through a quadrangular space which is bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally. It curves round the humeral neck and supplies the shoulder joint, deltoid, teres major and minor, and long and lateral heads of triceps. It gives off a descending branch which anastomoses with the deltoid branch of the profunda brachii artery and with the anterior circumflex humeral and acromial branches of the suprascapular and thoraco-acromial arteries.

Variants

Branches exhibit considerable variation. An alar thoracic artery, often from the second part, may supply fat and lymph nodes in the axilla. The lateral thoracic artery may be absent, in which case it is replaced by lateral perforating branches of the intercostal arteries, alternatively, it may become, or give off, a direct cutaneous vessel (named the superficial thoracic artery by some sources) which supplies the skin over the lateral border of pectoralis major. In up to 30% of cases, the subscapular artery can arise from a common trunk with the posterior circumflex humeral artery. Occasionally the subscapular, circumflex humeral and profunda brachii arteries arise in common, in which case, branches of the brachial plexus surround this common vessel instead of
the axillary artery. The posterior circumflex humeral artery may arise from the profunda brachii artery, and pass back below teres major instead of passing through the quadrangular space. Sometimes the axillary divides into radial and ulnar arteries (anomalous "high division"), and is occasionally the source of the anterior interosseous artery.
VEINS

Axillary vein

The axillary vein is the continuation of the basilic vein. It begins at the lower border of teres major, and ascends to the outer border of the first rib, where it becomes the subclavian vein. It is joined by the brachial vein near subscapularis, and by the cephalic vein near its costal end; other tributaries follow the axillary arterial branches. It lies medial to the axillary artery, which it partly overlaps. The medial pectoral nerve, medial cord of the brachial plexus, ulnar nerve and medial cutaneous nerve of the forearm lie between the artery and the vein. The medial cutaneous nerve of the arm is medial to the vein; the lateral group of axillary lymph nodes is posteromedial. There are a pair of valves near its distal end, and valves also occur near the ends of the cephalic and subscapular veins.

Subclavian vein

The subclavian vein is a continuation of the axillary vein. It extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular to form the brachiocephalic vein. The clavicle and subclavius are anterior, the subclavian artery is posterosuperior, separated by scalenus anterior and the phrenic nerve, and the first rib and pleura are inferior. The vein usually has a pair of valves about 2cm from its end. Its tributaries are the external jugular, dorsal scapular and (sometimes) anterior jugular veins, and occasionally a small branch from the cephalic vein which ascends anterior to the clavicle. At its junction with the internal jugular vein, the left subclavian receives the thoracic duct: the right subclavian vein receives the right lymphatic duct.
AXILLARY LYMPH NODES

There are between 20 to 30 axillary nodes, which may be divided into five not wholly distinct groups, namely, lateral, anterior (pectoral), posterior (subscapular), central and apical (Fig. 54.21, Fig. 45.6, Fig. 46.28). Four of the groups are intermediary, and only the apical group is terminal. Collectively they drain the entire upper limb, breast and trunk above the umbilicus.

The lateral group of four to six nodes is posteromedial to the axillary vein, its afferents drain the whole limb except the vessels accompanying the cephalic vein (Fig. 54.21, Fig. 45.6, Fig. 46.28). Efferent vessels pass partly to the central and apical axillary groups, and partly to the inferior deep cervical nodes. The anterior group of four or five nodes spreads along the inferior border of pectoralis minor near the lateral
thoracic vessels. Their afferents drain the skin and muscles of the supraumbilical anterolateral body wall and breast, and efferents pass partly to the central and partly to the apical axillary nodes. The posterior group of six or seven nodes lie on the inferior margin of the posterior axillary wall, along the subscapular vessels. Their afferents drain the skin and superficial muscles of the inferior posterior region of the neck and the dorsal aspect of the trunk down to the iliac crest, and efferents pass to the apical and central axillary nodes. A central group of three or four large nodes embedded in axillary fat receives afferents from all preceding groups, and their efferents drain to the apical nodes. An apical group of six to twelve nodes is partly posterior to the superior part of pectoralis minor and partly above its superior border, extending to the apex of the axilla medial to the axillary vein. The only direct territorial afferents are those which accompany the cephalic vein or some which drain the upper peripheral region of the breast: the group drains all the other axillary nodes. Their efferents unite as the subclavian trunk and drain directly to the jugulosubclavian venous junction, or the subclavian vein, or jugular lymphatic trunk or (occasionally) to a right lymphatic duct; the left trunk usually ends in the thoracic duct. A few efferents from apical nodes usually reach the inferior deep cervical nodes.

One or two infraclavicular nodes appear beside the cephalic vein, in the groove between pectoralis major and deltoid, just inferior to the clavicle. Their efferents pass through the clavipectoral fascia to the apical axillary nodes. Occasionally some pass anterior to the clavicle to the inferior deep cervical (supraclavicular) nodes.
INNERVATION

BRACHIAL PLEXUS

For an overview of the brachial plexus see page 779 and Fig. 45.7.

In the axilla, the lateral and posterior cords of the brachial plexus are lateral to the first part of the axillary artery, and the medial cord is behind the artery. The cords surround the second part of the artery, their names indicating their relationship. In the lower axilla the cords divide into nerves that supply the upper limb (Fig. 46.29). Other than the medial root of the median nerve, these nerves are related to the third part of the artery in the same way as their cords are related to the second part, i.e. branches of the lateral cord are lateral to the artery, branches of the medial cord are medial, and branches of the posterior cord are posterior.

Fig. 46.29 The brachial plexus, its branches and the muscles which they supply. The axillary artery, shown in red outline, runs anterior to the radial nerve. The vertebral levels are labelled C4–T2. The nerve roots are labelled C5–T1 (white circles).

Branches of the brachial plexus may be described as supraclavicular and infraclavicular.

Supraclavicular branches
Supraclavicular branches arise from roots or from trunks as follows:

</tbody>
</table>

Branches to the scaleni and longus colli arise from the lower cervical ventral rami near their exit from the intervertebral foramina. The phrenic nerve is joined by a branch from the fifth cervical ramus anterior to scalenus anterior.

**Dorsal scapular nerve**

The dorsal scapular nerve comes from the fifth cervical ventral ramus, pierces scalenus medius, passes behind levator scapulae, which it occasionally supplies, and runs with the deep branch of the dorsal scapular artery to the rhomboids, which it supplies.

**Long thoracic nerve**

The long thoracic nerve is usually formed by roots from the fifth to the seventh cervical rami, although the last ramus may be absent (Fig. 46.30). The upper two roots pierce scalenus medius obliquely, uniting in or lateral to it. The nerve descends dorsal to the brachial plexus and the first part of the axillary artery and crosses the superior border of serratus anterior to reach its lateral surface. It may be joined by the root from C7, which emerges between scalenus anterior and scalenus medius, and descends on the lateral surface of medius. The nerve continues downwards to the lower border of serratus anterior, and supplies branches to each of its digitations.
The long thoracic nerve is the most common nerve to be affected by neuralgic amyotrophy. Winging of the scapula may be the only clinical manifestation: it is best demonstrated by asking the patient to push against resistance with the arm extended at the elbow and flexed to 90° at the shoulder.

**Nerve to subclavius**

The nerve to subclavius is small and arises near the junction of the fifth and sixth cervical ventral rami. It descends anterior to the plexus and the third part of the subclavian artery and is usually connected to the phrenic nerve. It passes above the subclavian vein to supply subclavius.

**Suprascapular nerve**

The suprascapular nerve is a large branch of the superior trunk (Fig. 28.17). It runs laterally, deep to trapezius and omohyoid and enters the supraspinous fossa through the suprascapular notch inferior to the superior transverse scapular ligament. It runs deep to supraspinatus, supplies it, and curves round the lateral border of the spine of the scapula with the suprascapular artery to reach the infraspinous fossa, where it gives two branches to infraspinatus and articular rami to the shoulder and acromioclavicular joints. The suprascapular nerve rarely has a cutaneous branch. When present, it pierces deltoit close to the tip of the acromion and supplies the skin of the proximal third of the arm within the territory of the axillary nerve.

**Lesions of the suprascapular nerve**

The commonest cause involving the suprascapular nerve is neuralgic amyotrophy. An entrapment neuropathy may occur in the scapular notch, often related to a degenerate cyst originating from the posterior glenoid labrum, or the nerve may be damaged by
trauma to the scapula and shoulder. There is pain in the shoulder and wasting and weakness of supraspinatus and infraspinatus.

**Infraclavicular branches**

Infraclavicular branches come from the cords, but their axons may be traced back to the spinal nerves detailed in the box below.

**Lateral pectoral nerve**

The lateral pectoral nerve is larger than the medial, and may arise from the anterior divisions of the upper and middle trunks, or by a single root from the lateral cord. Its axons are from the fifth to seventh cervical rami. It crosses anterior to the axillary artery and vein, pierces the clavipectoral fascia and supplies the deep surface of pectoralis major. It sends a branch to the medial pectoral nerve, forming a loop in front of the first part of the axillary artery (Fig. 46.30), to supply some fibres to pectoralis minor.

**Medial pectoral nerve**

The medial pectoral nerve is derived from the eighth cervical and first thoracic ventral rami and branches from the medial cord while the latter lies posterior to the axillary artery. It curves forwards between the axillary artery and vein. Anterior to the artery it joins a ramus of the lateral pectoral nerve, and enters the deep surface of pectoralis minor, which it supplies. Two or three branches pierce pectoralis minor and others may pass round its inferior border to end in pectoralis major.

**Upper (superior) subscapular nerve**

The superior subscapular nerve is smaller than the inferior. It arises from the posterior cord (C5 and 6), enters subscapularis at a high level, and is frequently double.

**Lower (inferior) subscapular nerve**

The inferior subscapular nerve arises from the posterior cord (C5 and 6). It supplies the lower part of subscapularis, and ends in teres major, which is sometimes supplied
by a separate branch.

**Thoracodorsal nerve**

The thoracodorsal nerve arises from the posterior cord (C6 to 8) between the subscapular nerves. It accompanies the subscapular artery along the posterior axillary wall and supplies latissimus dorsi, reaching its distal border.

**Axillary nerve**

The axillary nerve arises from the posterior cord (C5, 6) (Fig. 46.22). It is at first lateral to the radial nerve, posterior to the axillary artery and anterior to subscapularis. At the lower border of subscapularis it curves back inferior to the humeroscapular articul means and, with the posterior circumflex humeral vessels, traverses a quadrangular space bounded above by subscapularis (anterior) and teres minor (posterior), below by teres major, medially by the long head of triceps, and laterally by the surgical neck of the humerus. It divides in the space into anterior and posterior branches. The anterior branch curves round the neck of the humerus with the posterior circumflex humeral vessels, deep to deltoid. It reaches the anterior border of the muscle and supplies it, and gives off a few small cutaneous branches which pierce deltoid and ramify in the skin over its lower part. The posterior branch courses medially and posteriorly along the attachment of the lateral head of triceps, inferior to the glenoid rim. It usually lies medial to the anterior branch in the quadrangular space. It gives off the nerve to teres minor and the upper lateral cutaneous nerve of the arm at the lateral edge of the origin of the long head of triceps. The nerve to teres minor enters the muscle on its inferior surface. The posterior branch frequently supplies the posterior aspect of deltoid, usually via a separate branch from the main stem, occasionally from the superior lateral cutaneous nerve of the arm. However, the posterior part of deltoid has a more consistent supply from the anterior branch of the axillary nerve, which should be remembered when performing a posterior deltoid-splitting approach to the shoulder. The upper lateral cutaneous nerve of the arm pierces the deep fascia at the medial border of the posterior aspect of deltoid and supplies the skin over the lower part of deltoid and the upper part of the long head of triceps. The posterior branch is intimately related to the inferior aspects of the glenoid and shoulder joint capsule, which may place it at particular risk during capsular plication or thermal shrinkage procedures (Ball et al 2003). There is often an enlargement or pseudoganglion on the branch to teres minor. The axillary trunk supplies a branch to the shoulder joint below subscapularis.

**Lesions of the axillary nerve**

The commonest causes of axillary nerve lesions are trauma (dislocation of the shoulder, fracture of the surgical neck of the humerus), and neuralgic amyotrophy. There is wasting and weakness of deltoid, which is usually clinically evident, and a patch of sensory loss on the outer aspect of the arm. This can be differentiated from a C5 root lesion by finding normal function in the distribution of the suprascapular nerve.

**Musculocutaneous nerve**

The musculocutaneous nerve arises from the lateral cord (C5–7), opposite the lower border of pectoralis minor (Fig. 46.30). It pierces coracobrachialis and descends laterally between biceps and brachialis to the lateral side of the arm. Just below the
elbow it pierces the deep fascia lateral to the tendon of biceps, and continues as the lateral cutaneous nerve of the forearm. A line drawn from the lateral side of the third part of the axillary artery across coracobrachialis and biceps to the lateral side of the biceps tendon is a surface projection for the nerve (but this varies according to its point of entry into coracobrachialis). It supplies coracobrachialis, both heads of biceps and most of brachialis. The branch to coracobrachialis is given off before the musculocutaneous nerve enters the muscle: its fibres are from the seventh cervical ramus and may branch directly from the lateral cord. Branches to biceps and brachialis leave after the musculocutaneous has pierced coracobrachialis: the branch to brachialis also supplies the elbow joint. The musculocutaneous nerve supplies a small branch to the humerus, which enters the shaft with the nutrient artery.

Lesions of the musculocutaneous nerve

An isolated lesion of the musculocutaneous nerve is rare, but may occur in injuries to the upper arm and shoulder, e.g. fracture of the humerus, and in patients with neuralgic amyotrophy. There is marked weakness of elbow flexion, because biceps brachii and much of brachialis are paralysed, and sensory impairment on the extensor aspect of the forearm in the distribution of the lateral cutaneous nerve of the forearm. Pain and paraesthesiae may be aggravated by elbow extension.

Medial cutaneous nerve of arm

The medial cutaneous nerve of the arm is the smallest and most medial branch of the brachial plexus, and arises from the medial cord (C8, T1). It crosses the axilla, either anterior or posterior to the axillary vein, then passes medial to the axillary vein, communicates with the intercostobrachial nerve, and descends medial to the brachial artery and basilic vein. It pierces the deep fascia at the midpoint of the upper arm to supply the skin over the medial aspect of the distal third of the upper arm.

Medial cutaneous nerve of forearm

The medial cutaneous nerve of the forearm arises from the medial cord (C8, T1). It is described further on pages 830 and 856.

Median nerve

The median nerve has two roots from the lateral (C5, 6, 7) and medial (C8, T1) cords, which embrace the third part of the axillary artery, and unite anterior or lateral to it (Fig. 46.30). Some fibres from C7 often leave the lateral root in the lower part of the axilla and pass distomedially posterior to the medial root, and usually anterior to the axillary artery, to join the ulnar nerve. They may branch from the seventh cervical ventral ramus. Clinically they are believed to be mainly motor and to supply flexor carpi ulnaris. If the lateral root is small, the musculocutaneous nerve (C5, 6, 7) connects with the median nerve in the arm.

Ulnar nerve

The ulnar nerve arises from the medial cord (C8, T1) but often receives fibres from the ventral ramus of C7 (Fig. 46.30). It runs distally through the axilla medial to the axillary artery, between it and the vein. It is described further on page 827.
Radial nerve

The radial nerve is the largest branch of the brachial plexus. It arises from the posterior cord (C5, 6, 7, 8, (T1)) (Fig. 46.22), and descends behind the third part of the axillary artery and the upper part of the brachial artery, anterior to subscapularis and the tendons of latissimus dorsi and teres major. With the profunda brachii artery it inclines dorsally, and passes through the triangular space below the lower border of teres major, between the long head of triceps and the humerus. It is described further on page 827.

Brachial plexus lesions

Lesions of the brachial plexus commonly affect either the upper part of the plexus, i.e. C5 and C6 roots and the upper trunk, or the lower part of the plexus, i.e. C8 and T1 roots and the lower trunk. Lesions affecting the upper part are usually traumatic, whereas those affecting the lower part may be caused by trauma but may also be produced by malignant infiltration or a thoracic outlet syndrome. Severe trauma may affect the whole plexus.

Upper plexus palsies

Downward traction of an infant's arm during birth, or, in adults, a severe fall on the side of the head and the shoulder, forcing the two apart, as frequently occurs in motor cycle injuries, may tear the roots of C5 and C6. This will result in paralysis of deltoid, the short muscles of the shoulder, and of brachialis and biceps. The last two are both elbow flexors, and biceps is also a powerful supinator of the superior radio-ulnar joint. The arm therefore hangs by the side, with the forearm pronated and the palm facing backwards, like a waiter hinting for a tip (Erb–Duchenne paralysis). There is sensory loss over the lateral aspect of the upper arm.

Lower plexus palsies

Upward traction on the arm, e.g. in a forcible breech delivery, may tear the lowest root, T1, which provides the segmental supply to the intrinsic muscles of the hand. The hand assumes a clawed appearance reflecting the unopposed action of the long flexors and extensors of the fingers (Klumpke's paralysis). There is sensory loss along the medial aspect of the forearm and there is often an associated Horner's syndrome (ptosis and constriction of the pupil) which occurs as a result of traction on the cervical sympathetic chain. Malignant infiltration of the brachial plexus may result from extension of an apical lung carcinoma (Pancoast tumour) or from metastatic spread, often from carcinoma of the breast. There is slowly progressive weakness which usually starts in the small muscles of the hand (T1) and spreads to involve the finger flexors (C8). This is usually a painful condition, and the pain may be severe. There is sensory loss on the medial aspect of the forearm (T1) extending into the medial side of the hand and to the little finger (C8). A Horner's syndrome may occur if there is involvement of the cervical sympathetic ganglia. A similar syndrome may occur following radiotherapy for breast carcinoma, but this is usually painless. Thoracic surgery involving a sternal split may cause traction on the brachial plexus and usually affects the lower part of the plexus.

The lower trunk of the brachial plexus (C8, T1), together with the subclavian artery,
may be angulated over a cervical rib (thoracic outlet syndrome). Patients may present with vascular symptoms as a result of kinking of the subclavian artery (this is more likely to occur with large bony ribs), or they may present with neurological deficit (this is more likely in patients with small rudimentary ribs which extend into a fibrous band which joins the first rib anteriorly). Cervical ribs are quite common and are rarely associated with symptoms. There is a slow insidious onset of wasting of the small muscles of the hand, which often starts on the lateral side with involvement of the thenar eminence and first dorsal interosseous. There is pain and paraesthesiae in the medial aspect of the forearm extending to the little finger, and this is often aggravated by carrying shopping or suitcases. A bruit may be heard over the subclavian artery, and the radial pulse may be easily obliterated by movements of the arm, particularly with the arm extended and abducted at the shoulder.

SKIN AND SOFT TISSUE

SKIN

Cutaneous vascular supply

The blood supply to the skin of the upper arm can be divided into three regions with separate supply: the deltoid region, supplied by musculocutaneous perforators, and the medial and lateral regions, supplied by fasciocutaneous perforators (Cormack & Lamberty 1994; Salmon 1994) (Fig. 47.1, Fig. 47.2).
The deltoid region is supplied by the posterior circumflex humeral artery (p. 817) via musculocutaneous perforators. After the posterior circumflex humeral artery passes through the quadrangular space (p. 814) it gives off a descending branch, which runs down to the deltoid insertion and the overlying skin, and an ascending branch which passes superiorly towards the acromion, pierces the edge of deltoid and the deep fascia to fan out and supply the overlying skin.

The medial side of the upper arm is supplied by five or six fasciocutaneous perforators which arise from the brachial artery, the superior ulnar collateral artery and, if present, the single artery to biceps. These perforators pass along the medial intermuscular septum to spread out in the deep fascia and anastomose with perforating vessels superiorly and inferiorly and from the lateral side. There are virtually no
musculocutaneous perforators through biceps or triceps.

The lateral side of the upper arm below deltoid is supplied by perforating vessels from the middle collateral and radial collateral arteries (the terminating bifurcation of the profunda brachii). The middle collateral artery sends perforators to the skin via the lateral intermuscular septum between brachioradialis and triceps, while the radial collateral artery gives off cutaneous perforators via the intermuscular septum between brachialis and brachioradialis. These cutaneous vessels anastomose with those from the medial side.

Cutaneous innervation

The skin of the shoulder region is supplied by the supraclavicular nerves from the cervical plexus. The floor of the axilla and upper medial surface of the arm is supplied by the lateral branch of the second intercostal nerve (the intercostobrachial nerve). The lower aspect of the medial side of the upper arm is supplied by the medial cutaneous nerve of the arm. The lateral aspect of the upper arm is supplied by the upper lateral cutaneous nerve (a branch of the axillary nerve) and the lower lateral cutaneous nerve (a branch of the radial nerve). The posterior aspect is supplied by the posterior cutaneous nerve of the arm, a branch of the radial nerve (Fig. 45.15, Fig. 45.14).
SOFT TISSUE

Brachial fascia

Brachial fascia, the deep fascia of the upper arm, is continuous with the fascia covering deltoid and pectoralis major: it forms a thin, loose sheath for muscles of the upper arm, and sends septa between them. It is thin over biceps, but thicker over triceps and the humeral epicondyles, and is strengthened by fibrous aponeuroses from pectoralis major and latissimus dorsi medially and from deltoid laterally. Strong medial and lateral intermuscular septa extend from it on each side.

The lateral intermuscular septum extends distally from the lateral lip of the intertubercular sulcus of the humerus along the lateral supracondylar ridge to the lateral epicondyle, and blends with the tendon of deltoid. It gives attachment to triceps behind, and brachialis, brachioradialis and extensor carpi radialis longus in front. It is perforated in the middle third by the radial nerve and the radial collateral branch of the profunda brachii artery. The thicker medial intermuscular septum extends from the medial lip of the intertubercular sulcus, distal to teres major, along the medial supracondylar ridge to the medial epicondyle, and blends with the tendon of coracobrachialis. It gives attachment to triceps behind, and brachialis in front. It is perforated by the ulnar nerve, superior ulnar collateral artery, and the posterior branch of the inferior ulnar collateral artery. At the elbow, the brachial fascia is attached to the epicondyles of the humerus and the olecranon of the ulna, and is continuous with the antebrachial fascia. Medially, just below the middle of the upper arm, it is traversed by the basilic vein and lymphatic vessels and, at various levels, branches of the brachial cutaneous nerves.

Together, the lateral and medial intermuscular septa of the upper arm divide the upper arm into anterior and posterior compartments.
MUSCLES

The muscles of the upper arm are coracobrachialis, which acts only on the shoulder joint; biceps and triceps, which cross both shoulder and elbow joints; and brachialis, which acts only at the elbow joint (Fig. 47.2, Fig. 47.3).

**Fig. 47.3** Muscles, vessels and nerves of the left upper arm, viewed from the posterior aspect. (From Sobotta 2006.)
Coracobrachialis

Attachments

Coracobrachialis arises from the apex of the coracoid process, together with the tendon of the short head of biceps, and also by muscular fibres from the proximal 10 cm of this tendon; it ends on an impression, 3–5 cm in length, midway along the medial border of the humeral shaft between the attachments of triceps and brachialis (Fig. 46.20, Fig. 47.4). Accessory slips may be attached to the lesser tubercle, medial epicondyle or medial intermuscular septum.
Fig. 47.4  A. Transverse section through the left arm a little below the middle of the shaft of the humerus. B. MRI scan at similar level.

Relations

Coracobrachialis forms an inconspicuous rounded ridge on the upper medial side of the arm; pulsation of the brachial artery can be felt and often seen in the depression behind it. The muscle is perforated by the musculocutaneous nerve. Anteriorly it is related to pectoralis major above and, at its humeral insertion, to the brachial vessels and median nerve, which cross it. The
tendons of subscapularis, latissimus dorsi, and teres major, the medial head of triceps, the humerus and the anterior circumflex humeral vessels all lie posterior. The axillary artery (third part) and proximal parts of the median and musculocutaneous nerves lie medial. Biceps and brachialis lie lateral.

**Vascular supply**

One or more branches from the axillary artery pass deep to the lateral root of the median nerve, and the musculocutaneous nerve, to reach the deep surface of the muscle. Branches from the anterior circumflex humeral artery also supply the deep surface of the muscle. The accompanying artery of the musculocutaneous nerve sends a recurrent branch to the coracoid attachment and gives off a series of branches to the muscle during its intramuscular course. Accessory branches from the thoracoacromial artery provide additional supply to the superficial part of coracobrachialis.

**Innervation**

Coracobrachialis is innervated by the musculocutaneous nerve, C5, 6 and 7.

**Actions**

Coracobrachialis flexes the arm forward and medially, especially from a position of brachial extension. In abduction it acts with anterior fibres of deltoid to resist departure from the plane of motion.

**Clinical anatomy: testing**

Coracobrachialis can be tested by palpating its fibres during shoulder flexion against resistance.

**Biceps brachii**

**Attachments**

Biceps brachii derives its name from its two proximally attached parts or ‘heads’ (Fig. 46.20). The short head arises by a thick flattened tendon from the coracoid apex, together with coracobrachialis. The long head starts within the capsule of the shoulder joint as a long narrow tendon, running from the supraglenoid tubercle of the scapula at the apex of the glenoidal cavity, where it is continuous with the glenoidal labrum (p. 805). The tendon of the long head, enclosed in a double tubular sheath (an extension of the synovial membrane of the joint capsule), arches over the humeral head, emerges from the joint behind the transverse humeral ligament, and descends in the intertubercular sulcus, where it is retained by the transverse humeral ligament and a fibrous expansion from the tendon of pectoralis major. The two tendons lead into elongated bellies that, although closely applied, can be separated to within 7 cm or so of the elbow joint. At this joint they end in a
flattened tendon, which is attached to the rough posterior area of the radial tuberosity; a bursa separates the tendon from the smooth anterior area of the tuberosity. As it approaches the radius, the tendon spirals, its anterior surface becoming lateral before being applied to the tuberosity. The tendon has a broad medial expansion, the bicipital aponeurosis, which descends medially across the brachial artery to fuse with deep fascia over the origins of the flexor muscles of the forearm (Fig. 47.5). The tendon can be split without difficulty as far as the tuberosity, whence it can be confirmed that its anterior and posterior layers receive fibres from the short and long heads, respectively.
In 10% of cases, a third head arises from the superomedial part of brachialis and is attached to the bicipital aponeurosis and medial side of the tendon of insertion. It usually lies behind the brachial artery, but it may consist of two slips, which descend in front of and behind the artery. Less often, other slips may spring from the lateral aspect of the humerus or intertubercular sulcus.

Relations

Biceps is overlapped proximally by pectoralis major and deltoid; distally it is covered only by fasciae and skin, and it forms a conspicuous elevation on the front of the arm. Its long head passes through the shoulder joint; its short head is anterior to the joint. Distally it lies anterior to brachialis, the musculocutaneous nerve and supinator. Its medial border touches coracobrachialis, and overlaps the brachial vessels and median nerve; its lateral border is related to deltoit and brachioradialis.

Vascular supply

Biceps brachii is typically supplied by up to eight vessels originating from the brachial artery in the middle third of the arm. These vessels pass laterally, posterior to the median nerve and divide into ascending and descending branches just before reaching the deep surface of the muscle. Smaller branches arise from the anterior circumflex humeral artery and the deltoid branch of the acromial division of the thoracoacromial axis.

There is great variation in the arterial supply to the muscle. The main arterial supply may originate from the superior or inferior ulnar collateral artery, subscapular artery, axillary artery, ulnar or radial arteries in cases of proximal bifurcation of the brachial artery, or the profunda brachii artery.

Innervation

Biceps brachii is innervated by the musculocutaneous nerve, C5 and 6, with separate branches passing to each belly.

Actions

Biceps brachii is a powerful supinator, especially in rapid or resisted movements. It flexes the elbow, most effectively with the forearm supinated, and acts to a slight extent as a flexor of the shoulder joint. It is attached, via the bicipital aponeurosis, to the posterior border of the ulna, the distal end of which is drawn medially in supination. The long head helps to check upward
translation of the humeral head during contraction of deltoid. When the elbow is flexed against resistance, the tendon of insertion and bicipital aponeurosis become conspicuous.

Lowering the hand under the influence of gravity by extension at the elbow calls for controlled lengthening of biceps. This is an example of a habitual movement in which muscle tension increases despite increasing length. As the hand descends and the elbow extends, the vertical through the centre of gravity of the forearm is carried further from the fulcrum of movement; the turning moment exerted by the load therefore increases and must be matched by an increase in the moment exerted by the muscle.

Clinical anatomy: testing

With the forearm supinated, biceps brachii can be tested by palpating its fibres during elbow flexion against resistance.

**Brachialis**

**Attachments**

Brachialis arises from the lower half of the front of the humerus, starting on either side of the insertion of deltoid, and extending distally to within 2.5 cm of the cubital articular surface (Fig. 46.20, Fig. 47.4). It also arises from the intermuscular septa, more from the medial than the lateral, since it is separated distally from the lateral intermuscular septum by brachioradialis and extensor carpi radialis longus. Its fibres converge to a thick, broad tendon which is attached to the ulnar tuberosity and to a rough impression on the anterior aspect of the coronoid process.

Brachialis may be divided into two or more parts. It may be fused with brachioradialis, pronator teres or biceps. In some cases it sends a tendinous slip to the radius or bicipital aponeurosis.

**Relations**

Anterior are biceps, the brachial vessels, musculocutaneous and median nerves. Posterior are the humerus and capsule of the elbow joint. Medial are pronator teres, and the medial intermuscular septum, which separates it from triceps and the ulnar nerve. Lateral are the radial nerve, radial recurrent and radial collateral arteries, brachioradialis and extensor carpi radialis longus.

**Vascular supply**

The blood supply to brachialis typically consists of two main arteries (superior and inferior) supplemented by a system of accessory arteries. The superior main artery originates from the brachial artery distal to the site of origin of the
superior ulnar collateral artery and travels laterally to enter the anterior surface of the upper third of the muscle. The inferior main artery originates either from the superior ulnar collateral artery or directly from the brachial artery and enters the mid-portion of the muscle. The accessory arteries are small, variable in number, origin and course. They can arise from the brachial artery, the superior and inferior ulnar collateral arteries, or the profunda brachii artery.

Innervation

Brachialis is innervated by the musculocutaneous nerve (C5 and 6), and radial nerve (C7) to a small lateral part of the muscle.

Action

Brachialis is a flexor of the elbow joint with the forearm either prone or supine, whether or not the movement is resisted.

Clinical anatomy: testing

Brachialis can be tested by palpating its fibres during elbow flexion against resistance.
POSTERIOR COMPARTMENT

Triceps

Attachments

Triceps fills most of the extensor compartment of the upper arm (Fig. 46.22, Figs 47.2–47.4). It arises by three heads (long, lateral and medial), from which it takes its name.

The long head arises by a flattened tendon from the infraglenoid tubercle of the scapula, blending above with the glenohumeral capsule. Its muscular fibres descend medial to the lateral head and superficial to the medial head, and join them to form a common tendon.

The lateral head arises by a flattened tendon from a narrow, linear, oblique ridge on the posterior surface of the humeral shaft, and from the lateral intermuscular septum. The origin on the humerus ascends with varying obliquity from its lateral border above the radial groove and behind the deltoid tuberosity to the surgical neck medial to the insertion of teres minor. These fibres also converge to the common tendon.

The medial head, which is overlapped posteriorly by the lateral and long heads, has a particularly extensive origin, from the entire posterior surface of the humeral shaft, below the radial groove from the insertion of teres major to within 2.5 cm of the trochlea, from the medial border of the humerus; the medial intermuscular septum and the lower part of the lateral intermuscular septum. Some muscular fibres reach the olecranon directly, the rest converge to the common tendon.

The tendon of triceps begins near the middle of the muscle. It has two laminae, one superficial in the lower half of the muscle, the other in its substance. After receiving the muscle fibres, the two layers unite above the elbow and are attached, for the most part, to the upper surface of the olecranon. On the lateral side a band of fibres continues down over anconeus to blend with antebrachial fascia.

Relations

The long head descends between teres minor and major, dividing the wedge-shaped interval between them and the humerus into triangular and quadrangular parts (Fig. 46.22). The triangular space contains the circumflex scapular vessels; it is bounded above by teres minor, below by teres major, laterally by the long head of triceps. The quadrangular space transmits the posterior circumflex humeral vessels and the axillary nerve; it is bounded above by subscapularis, teres minor and the articular capsule, below by teres
major, medially by the long head of triceps, and laterally by the humerus.

The lateral head of triceps forms an elevation, parallel and medial to the posterior border of the deltoid; it stands out prominently when the elbow is actively extended. The mass which lies medial to it, and disappears under the deltoid, is the long head.

Vascular supply

The blood supply to triceps is mainly from the profunda brachii artery and the superior ulnar collateral artery, with an accessory supply from the posterior circumflex humeral artery. The medial head of triceps is supplied on its anterior surface by two or three branches from the superior ulnar collateral artery. The posterior surface is supplied by a large proximal branch from the profunda which passes medially in front of the radial nerve. The long head of triceps is supplied on its anterior surface by two arteries, one arising from the axillary artery in front of the tendon of latissimus dorsi and the other arising from either the brachial artery or the superior ulnar collateral. The posterior surface receives a recurrent branch from the posterior circumflex humeral artery immediately after traversing the quadrangular space. The lateral surface receives a number of small branches from the profunda brachii in its distal portion. The lateral head of the triceps is primarily supplied by branches of the profunda brachii, with an additional supply from a branch of the posterior circumflex humeral artery.

Innervation

Triceps is innervated by the radial nerve, C6, 7 and 8, with separate branches for each head.

Action

Triceps is the major extensor of the forearm at the elbow joint. The medial head is active in all forms of extension. The lateral and long heads are minimally active except in extension against resistance, as in thrusting or pushing or supporting body weight on the hands with the elbows semiflexed. When the flexed arm is extended at the shoulder joint, the long head may assist in drawing back and adducting the humerus to the thorax. The long head supports the lower part of the capsule of the shoulder joint, especially when the arm is raised. Articularis cubiti probably draws up the posterior part of the capsule of the elbow joint during extension of the forearm. In forceful supination of the semiflexed forearm, involving contraction of both supinator and biceps brachii, the triceps contracts synergistically to maintain the semiflexed position.

Clinical anatomy: testing
The muscle can be tested by palpating its fibres during elbow extension against resistance.

Anconeus

Anconeus is described on page 850.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIES

Brachial artery

The brachial artery, a continuation of the axillary, begins at the distal (inferior) border of the tendon of teres major and ends about a centimetre distal to the elbow joint (at the level of the neck of the radius) by dividing into radial and ulnar arteries (Fig. 47.5, Fig. 47.6). At first it is medial to the humerus, but gradually spirals anterior to it until it lies midway between the humeral epicondyles. Its pulsation can be felt throughout.
Fig. 47.6 The arterial anastomoses around the left elbow joint viewed from the anterior aspect. 
(From Drake, Vogl and Mitchell 2005.)

Relations

The brachial artery is wholly superficial, covered anteriorly only by skin and superficial and deep fasciae. The bicipital aponeurosis crosses it anteriorly at the elbow, separating it from the median cubital vein; the median nerve crosses it lateromedially near the distal attachment of coracobrachialis.
Posterior are the long head of triceps, separated by the radial nerve and profunda brachii artery, and then successively by the medial head of triceps, the attachment of coracobrachialis and brachialis. Proximally the median nerve and coracobrachialis lie laterally while distally the biceps and the muscles overlap the artery. Proximally the medial cutaneous nerve of the forearm and ulnar nerve lie medially, while distally the median nerve and basilic vein lie medially. With the artery are two venae comitantes, connected by transverse and oblique branches.

At the elbow the brachial artery sinks deeply into the triangular intermuscular cubital fossa (p. 831).

**Variants**

The brachial artery, with the median nerve, may diverge from the medial border of the biceps, descending towards the medial humeral epicondyle, usually behind a supracondylar process from which a fibrous arch crosses the artery, and which then runs behind or through pronator teres to the elbow. Occasionally the artery divides proximally into two trunks which reunite. Frequently it divides more proximally than usual into radial, ulnar and common interosseous arteries. Most often the radial branches arise proximally, leaving a common trunk for the ulnar and common interosseous arteries. Sometimes the ulnar arises proximally, the radial and common interosseous forming the other division; the common interosseous may also arise proximally. Sometimes slender vasa aberrantia connect the brachial to the axillary artery or to one of the forearm arteries, usually the radial. The brachial artery may be crossed by muscular or tendinous slips from coracobrachialis, biceps, brachialis or pronator teres. Rarely the median nerve crosses behind, and not in front of, the brachial artery near the insertion of coracobrachialis.

**Branches**

These are profunda brachii, nutrient, superior, middle and inferior ulnar collateral, deltoïd, muscular, radial and ulnar arteries.

**Profunda brachii artery**

The profunda brachii (Fig. 47.2, Fig. 47.3, Fig. 47.5, Fig. 47.6) is a large branch from the posteromedial aspect of the brachial artery, distal to teres major. It follows the radial nerve closely, at first posteriorly between the long and medial heads of triceps, then in the spiral groove covered by the lateral head of triceps. It supplies muscular branches, the nutrient artery of the humerus, and finally divides into terminal radial and middle collateral branches (Fig. 47.6). The radial collateral branch pierces the lateral intermuscular septum to reach the anterior aspect of the epicondyle of the humerus in the groove between brachioradialis and brachialis, and takes part
in the anastomosis around the elbow. The middle collateral branch runs posterior to the septum and epicondyle.

The profunda brachii can originate from a common origin with the posterior circumflex humeral artery, from the axillary artery proximal to the tendon of latissimus dorsi or from the distal portion of the axillary artery.

**Middle collateral (posterior descending) branch**

The middle collateral artery is the larger terminal vessel. It arises posterior to the humerus and descends down the posterior surface of the lateral intermuscular septum to the elbow (Fig. 47.4, Fig. 47.6). Proximally, the artery lies between brachialis (anteriorly) and the lateral head of triceps (posteriorly) while distally it lies between brachioradialis (anteriorly) and the lateral head of triceps (posteriorly). It may pierce the deep fascia and become cutaneous or remain deep to the fascia until anastomosing with the interosseous recurrent artery behind the lateral epicondyle; it gives off about five small fasciocutaneous perforators and often has a small branch that accompanies the nerve to anconeus.

This artery and its fasciocutaneous perforators provide the anatomical basis to allow a skin flap (the lateral arm flap) to be surgically raised (either pedicled or by free tissue transfer) for reconstructing areas of tissue missing elsewhere in the body.

**Radial collateral (anterior descending) branch**

The radial collateral artery is the continuation of the profunda (Fig. 47.6). It accompanies the radial nerve through the lateral intermuscular septum, descending between brachialis and brachioradialis anterior to the lateral epicondyle, anastomosing with the radial recurrent artery. It supplies brachialis, brachioradialis, the radial nerve and a few fasciocutaneous perforators.

**Nutrient artery of humerus**

The nutrient artery of the humerus arises near the mid-level of the upper arm, and enters the nutrient canal near the attachment of coracobrachialis, posterior to the deltoid tuberosity; it is directed distally.

**Superior ulnar collateral artery**

The superior ulnar collateral artery arises a little distal to the mid-level of the upper arm, usually from the brachial artery, but often as a branch from the profunda brachii (Figs 47.4–47.6). It accompanies the ulnar nerve, piercing the medial intermuscular septum to descend in the posterior compartment and supply the medial head of triceps. It passes between the medial
epicondyle and olecranon, ending deep to flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior collateral arteries. A branch sometimes passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery.

Fig. 47.7 Superficial veins and nerves of the left upper arm. (From Sobotta 2006.)

Middle ulnar collateral artery
If present, the middle ulnar collateral artery arises from the brachial artery between the superior and inferior ulnar collaterals. It passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery. It supplies triceps and sends small fasciocutaneous perforators to the skin.

Inferior ulnar collateral (supratrochlear) artery

The inferior ulnar collateral artery begins approximately 5 cm proximal to the elbow, passes medially between the median nerve and brachialis and, piercing the medial intermuscular septum, curls round the humerus between the triceps and bone (Fig. 47.5, Fig. 47.6). It forms, by its junction with the middle collateral branch of the profunda brachii artery, an arch proximal to the olecranon fossa. As it lies on brachialis it gives off branches which descend anterior to the medial epicondyle to anastomose with the anterior ulnar recurrent artery. Behind the epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

Muscular branches

Muscular branches are distributed to the coracobrachialis, biceps and brachialis.

Deltoid (ascending) branch

The deltoïd branch ascends between the lateral and long heads of triceps, and anastomoses with a descending branch of the posterior humeral circumflex artery.

Radial and ulnar arteries

The radial and ulnar arteries are described in detail on page 835.
VEINS

Brachial veins

The brachial veins flank the brachial artery, as venae comitantes with tributaries similar to the arterial branches; near the lower margin of subscapularis they join the axillary vein. The medial branch, however, often joins the basilic before it becomes the axillary.

These deep veins have numerous anastomoses with each other and with the superficial veins.

Superficial veins

The cephalic vein ascends in front of the elbow superficial to a groove between the brachioradialis and biceps, crosses superficial to the lateral cutaneous nerve of the forearm, ascends lateral to biceps and between pectoralis major and deltoid, where it adjoins the deltoid branch of the thoracoacromial artery (Fig. 45.5, Fig. 47.7). Entering the infraclavicular fossa to pass behind the clavicular head of pectoralis major, it pierces the clavipectoral fascia, crosses the axillary artery and joins the axillary vein just below clavicular level. It may connect with the external jugular by a branch anterior to the clavicle. Sometimes the median cubital vein is large, transferring most blood from the cephalic to the basilic vein; the proximal cephalic vein is then absent or much diminished.
LYMPHATIC DRAINAGE

Lymphatics follow the usual pattern in that superficial lymphatics follow the veins; deep lymphatics follow the arteries.

For details of supratrochlear nodes see page 836.

For details of infraclavicular nodes see page 818.
INNERVATION

Median nerve

The median nerve (Fig. 45.7, Fig. 47.5, Fig. 47.8) enters the arm lateral to the brachial artery. Near the insertion of coracobrachialis it crosses in front of (rarely behind) the artery, descending medial to it to the cubital fossa where it is posterior to the bicpital aponeurosis and anterior to brachialis, separated by the latter from the elbow joint.

Fig. 47.8 Anterior aspect of the left upper arm dissected to show the musculocutaneous nerve.
It gives off vascular branches to the brachial artery and usually a branch to pronator teres, a variable distance proximal to the elbow joint.

**Musculocutaneous nerve**

The musculocutaneous nerve is the nerve of the anterior compartment of the arm (Fig. 47.5, Fig. 47.8). It gives a branch to the shoulder joint and then passes through coracobrachialis, which it supplies, emerging to pass between biceps and brachialis. It sends branches to both these muscles. In the cubital fossa it lies at the lateral margin of the biceps tendon where it continues as the lateral cutaneous nerve of the forearm.

The musculocutaneous nerve has frequent variations. It may run behind coracobrachialis or adhere for some distance to the median nerve and pass behind biceps. Some fibres of the median nerve may run in the musculocutaneous nerve, leaving it to join their proper trunk; less frequently the reverse occurs, and the median nerve sends a branch to the musculocutaneous. Occasionally it supplies pronator teres and may replace radial branches to the dorsal surface of the thumb.

**Ulnar nerve**

The ulnar nerve gives no branches in the arm (Fig. 47.5, Fig. 47.8). It runs distally through the axilla medial to the axillary artery and between it and the vein, continuing distally medial to the brachial artery as far as the midarm. Here it pierces the medial intermuscular septum, inclining medially as it descends anterior to the medial head of triceps to the interval between the medial epicondyle and the olecranon, with the superior ulnar collateral artery.

**Radial nerve**

The radial nerve descends behind the third part of the axillary artery and the upper part of the brachial artery, anterior to subscapularis and the tendons of latissimus dorsi and teres major (Figs 47.2–47.4, Fig. 47.8). With the profunda brachii artery it inclines dorsally, passing through the triangular space (see p. 814) below the lower border of teres major, between the long head of triceps and the humerus. Here it supplies the long head of triceps, and gives rise to the posterior cutaneous nerve of the arm which supplies the skin along the posterior surface of the upper arm. It then spirals obliquely across the back of the humerus, lying posterior to the uppermost fibres of the medial head of triceps which separate the nerve from the bone in the first part of the spiral groove. Here it gives off a muscular branch to the lateral head of triceps and a branch which passes through the medial head of
triceps to anconeus. On reaching the lateral side of the humerus it pierces the lateral intermuscular septum to enter the anterior compartment; it then descends deep in a furrow between brachialis and proximally brachioradialis, then more distally extensor carpi radialis longus. Anterior to the lateral epicondyle it divides into superficial and deep terminal rami.

The branches of the radial nerve in the upper arm are: muscular, cutaneous, articular and superficial terminal and posterior interosseous.

Muscular branches

Muscular branches supply triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis in medial, posterior and lateral groups. Medial muscular branches arise from the radial nerve on the medial side of the arm. They supply the medial and long heads of triceps; the branch to the medial head is a long, slender filament which, lying close to the ulnar nerve as far as the distal third of the arm, is often termed the ulnar collateral nerve. A large posterior muscular branch arises from the nerve as it lies in the humeral groove. It divides to supply the medial and lateral heads of triceps and anconeus, that for the latter being a long nerve which descends in the medial head of triceps and partially supplies it; it is accompanied by the middle collateral branch of the profunda brachii artery and passes behind the elbow joint to end in anconeus. Lateral muscular branches arise in front of the lateral intermuscular septum; they supply the lateral part of brachialis, brachioradialis and extensor carpi radialis longus.

Cutaneous branches

Cutaneous branches are the posterior and lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

Lower lateral cutaneous nerve of the arm

The lower lateral cutaneous nerve of the arm perforates the lateral head of triceps distal to the deltoid tuberosity, passes to the front of the elbow close to the cephalic vein and supplies the skin of the lateral part of the lower half of the arm.

Posterior cutaneous nerve of the arm

The small posterior cutaneous nerve of the arm arises in the axilla and passes medially to supply the skin on the dorsal surface of the arm nearly as far as the olecranon. It crosses posterior to and communicates with the intercostobrachial nerve.

Posterior cutaneous nerve of the forearm
The posterior cutaneous nerve of the forearm arises with the lower lateral cutaneous nerve of the arm. Perforating the lateral head of triceps, it descends first lateral in the arm, then along the dorsum of the forearm to the wrist, supplying the skin in its course and joining, near its end, with dorsal branches of the lateral cutaneous nerve of the forearm.

*Articular branches to elbow joint*

See page 836.

*Lesions of the radial nerve in the upper arm*

Lesions of the radial nerve at its origin from the posterior cord in the axilla may be caused by pressure from a long crutch (crutch palsy). Triceps is only involved when lesions occur at this level and is usually spared in the more common lesions of the radial nerve in the arm as it lies alongside the spiral groove, where the nerve is commonly affected by fractures of the humerus. Compression of the nerve against the humerus occurs if the arm is rested on a sharp edge such as the back of a chair (‘Saturday night palsy’). Both these injuries cause weakness of brachioradialis with wasting and loss of the reflex. There is both wrist and finger drop due to weakness of wrist and finger extensors, as well as weakness of extensor pollicis longus and abductor pollicis longus. There may be sensory impairment or paraesthesiae in the distribution of the superficial radial nerve. However, nerve overlap means that only a small area of anaesthesia usually occurs on the dorsum of the hand between the first and second metacarpal bones.

*Medial cutaneous nerve of arm*

The medial cutaneous nerve of arm supplies the skin of the medial aspect of the arm (Fig. 47.7). It is the smallest branch of the brachial plexus, and arises from the medial cord and contains fibres from the eighth cervical and first thoracic ventral rami. It traverses the axilla, crossing anterior or posterior to the axillary vein, to which it is then medial, and communicating with the intercostobrachial nerve; it descends medial to the brachial artery and basilic vein (Fig. 47.7) to a point midway in the upper arm, where it pierces the deep fascia to supply a medial area in the distal third of the arm, extending on to its anterior and posterior aspects. Rami reach the skin anterior to the medial epicondyle, and over the olecranon. It connects with the posterior branch of the medial cutaneous nerve of the forearm. Sometimes the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected in a plexiform manner in the axilla. The intercostobrachial nerve may be large and reinforced by part of the lateral cutaneous branch of the third intercostal nerve. It then replaces the medial cutaneous nerve of the arm and receives a connection representing the latter from the brachial plexus (occasionally this connection is absent).
Medial cutaneous nerve of forearm

The medial cutaneous nerve of forearm comes from the medial cord (Fig. 47.7). It is derived from the eighth cervical and first thoracic ventral rami. At first it is between the axillary artery and vein and gives off a ramus which pierces the deep fascia to supply the skin over the biceps, almost to the elbow. The nerve descends medial to the brachial artery, pierces the deep fascia with the basilic vein midway in the arm and divides into anterior and posterior branches. The larger, anterior branch usually passes in front of, occasionally behind, the median cubital vein, descending anteromedial in the forearm to supply the skin as far as the wrist and connecting with the palmar cutaneous branch of the ulnar nerve. The posterior branch descends obliquely medial to the basilic vein, anterior to the medial epicondyle, and curves round to the back of the forearm, descending on its medial border to the wrist, supplying the skin. It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the dorsal branch of the ulnar.
REFERENCES

SKIN

Cutaneous vascular supply

The skin overlying the cubital fossa receives its blood supply on its anterolateral side by small perforating vessels from the radial collateral artery, together with some small musculocutaneous perforators from the radial recurrent artery which traverse brachioradialis (Fig. 45.4). On the anteromedial side, skin is supplied by small branches from the anastomosis between the inferior ulnar collateral artery and the anterior ulnar recurrent artery and by small branches from the brachial artery.

A plexus of anastomosing vessels covers the posterior aspect of the elbow region. On the medial side, the plexus is supplied by small branches from the superior and inferior ulnar collateral arteries and the posterior ulnar recurrent artery, and on the lateral side from the middle collateral artery and the posterior interosseous recurrent artery.

Cutaneous innervation

The skin of the cubital fossa and the epicondylar regions is innervated by the medial and lateral cutaneous nerves of the forearm (Fig. 45.15). A small proximal area on the lateral aspect is supplied by the distal part of the lower lateral cutaneous nerve of the arm. The skin over the olecranon region is innervated by the distal branches of the posterior cutaneous nerve of the arm, together with proximal branches of the posterior cutaneous nerve of the forearm.
SOFT TISSUE: CUBITAL FOSSA

The cubital fossa forms a triangular depression in the middle of the upper part of the anterior aspect of the forearm (Fig. 48.1). The superior border of the fossa is an imaginary line, which joins the two epicondyles of the humerus. The fleshy elevation which constitutes its medial border is formed by the lateral margin of pronator teres and the elevation which forms the lateral border is the medial edge of brachioradialis. The roof of the fossa is formed by the deep fascia of the forearm, reinforced by the bicipital aponeurosis on the medial aspect. The median cubital vein lies on this deep fascia crossed superficially (or sometimes deeply) by the medial cutaneous nerve of the forearm. Brachialis and supinator form the floor of the fossa.
Fig. 48.1 Anterior aspect of the left elbow, superficial structures. The subcutaneous veins have been cut to reveal the subfascial structures. Compare with Fig. 48.6.

From medial to lateral, the fossa contains the median nerve, the terminal part of the brachial artery together with the start of the radial and ulnar arteries and accompanying veins, the tendon of biceps and the radial nerve just under cover of brachioradialis.
JOINTS

The humerus articulates with both the radius and the ulna at the elbow joint. The radius and ulna articulate by synovial superior (proximal) and inferior (distal) radio-ulnar joints and by an intermediate interosseous membrane and ligament, which constitute a fibrous middle radio-ulnar union.

ELBOW JOINT

The elbow joint is a synovial joint. Its complexity is increased by continuity with the superior radio-ulnar joint. It includes two articulations (Fig. 48.2). These are the humero-ulnar, between the trochlea of the humerus and the ulnar trochlear notch, and the humero-radial, between the capitulum of the humerus and the radial head.

Fig. 48.2 A–D. The left elbow joint. A, Synovial cavity partially distended: anterior aspect. The fibrous capsule of the elbow joint has been removed but the thick part of the anular ligament has been left in situ. Note that the synovial membrane (blue) descends below the lower border of the anular ligament. B, Synovial cavity partially distended: posterior aspect of the specimen represented in A. In A and B a small part of the ulnar (medial) collateral ligament may be seen. C, Medial aspect. D, Lateral aspect.
Articulating surfaces

The articular surfaces are the humeral trochlea and capitulum, and the ulnar trochlear notch and radial head. The trochlea is not a simple pulley because its medial flange exceeds its lateral, thus projecting to a lower level. This means that the plane of the joint, approximately 2 cm distal to the inter-epicondylar line, is tilted inferomedially; the trochlea is also widest posteriorly where its lateral edge is sharp. The trochlear notch is not wholly congruent with it: in full extension the medial part of its upper half is not in contact with the trochlea and a corresponding lateral strip loses contact in flexion. The trochlea has an asymmetrical sellar surface, largely concave transversely, convex anteroposteriorly: sections show that these profiles are compounded spirals. Swing is therefore accompanied (as in all hinge joints) by screwing and conjunct rotation. The olecranon and coronoid parts of the trochlear notch are usually separated by a rough strip, devoid of articular cartilage and covered by fibroadipose tissue and synovial membrane. The capitulum and the radial head are reciprocally curved; closest contact occurs in midpronation with a semiflexed radius. The rim of the head, which is more prominent medially, fits the groove between humeral capitulum and trochlea.

The humero-ulnar and humero-radial articulations form a largely uniaxial joint which is one of the most congruent, and therefore most stable, joints in the body. The static soft tissue stability of the joint is derived from the anterior capsule and lunar and radial collateral ligaments.

Fibrous capsule

The fibrous capsule (Fig. 48.2, Fig. 48.3, 48.4) is broad and thin anteriorly. It is attached proximally to the front of the medial epicondyle and humerus above the coronoid and radial fossae, and distally to the edge of the ulnar coronoid process and anular ligament, and is continuous at its sides with the ulnar and radial collateral ligaments. Anteriorly it receives numerous fibres from brachialis. Posteriorly the capsule is thin and attached to the humerus behind its capitulum and near its lateral trochlear margin, to all but the lower part of the edge of the olecranon fossa, and to the back of the medial epicondyle. Inferomedially it reaches the superior and lateral margins of the olecranon and is laterally continuous with the superior radio-ulnar capsule deep to the anular ligament. It is related posteriorly to the tendon of triceps and to anconeus.
Ligaments

The humero-ulnar and humeroradial articulations have ulnar and radial collateral ligaments.

*Ulnar collateral ligament*

This is a triangular band, consisting of thick anterior, posterior and inferior parts united by a thin region (Fig. 48.2C). The strongest and stiffest anterior part is attached by its apex to the front of the medial epicondyle and by its broad distal base to a proximal tubercle on the medial coronoid margin. The posterior part, also triangular, is attached low on the back of the medial epicondyle and to the medial margin of the olecranon. Between these two bands intermediate fibres descend from the medial epicondyle to an inferior, oblique band, often weak, between the olecranon and coronoid processes. This converts a depression on the medial margin of the trochlear notch into a foramen, through which the intracapsular fat pad is continuous with extracapsular fat medial to the joint. The anterior band is taut throughout most of the range of flexion, while the posterior band becomes taut between half and full flexion.

The ulnar collateral ligament is related to triceps, flexor carpi ulnaris and the ulnar nerve. Along it, anteriorly, the attachment of flexor digitorum superficialis extends from the medial epicondyle to the medial coronoid border.

*Radial collateral ligament*

This is attached low on the lateral epicondyle and to the anular ligament (Fig. 48.2D). Some of its posterior fibres cross the ligament to the proximal end of the supinator crest of the ulna. It intimately blends with attachments of supinator and extensor carpi radialis brevis. It is taut throughout most of the range of flexion.

*Synovial membrane*

The synovial membrane (Figs 48.2–48.4) extends from the humeral articular margins, lines the coronoid, radial and olecranon fossae, the flat medial trochlear surface, the deep surface of the capsule and the lower part of the anular ligament. Projecting between the radius and ulna from behind is a crescentic synovial fold, which partly
divides the joint into humero-radial and humero-ulnar parts. Irregularly triangular, it contains extrasynovial fat (Fig. 48.5). Between the capsule and synovial membrane are three other pads of fat: the largest, at the olecranon fossa, is pressed into the fossa by triceps during flexion; the other two, at the coronoid and radial fossae, are pressed in by brachialis during extension. They are all slightly displaced in contrary movements. Smaller synovial-covered tags of fat project into the joint near constrictions flanking the trochlear notch, and cover small non-articular areas of bone.

**Fig. 48.5** The proximal left radio-ulnar joint. **A**, Transverse section. **B**, Axial MRI scan: 1. Superficial group of flexor
A small bursa, the olecranon bursa, lies between the elbow joint capsule and the insertion of triceps tendon. Pressure and friction can lead to inflammation and enlargement of this bursa.

Vascular supply and lymphatic drainage

Articular arteries are derived from the numerous periarticular anastomoses (Fig. 47.6).

Innervation

Articular nerves are mainly from branches of the musculocutaneous and radial nerves, but the ulnar, median, and sometimes anterior interosseous nerves also contribute. The musculocutaneous branch is from the nerve to brachialis and innervates an anterior part of the capsule; branches of the radial supply posterior and anterolateral regions and come from the nerve to anconeus and the ulnar collateral branch to the medial head of triceps. The ulnar nerve supplies the ulnar collateral ligament behind the medial epicondyle. These articular nerves accompany blood vessels supplying the synovial membrane, fat pads and epiphyses; they presumably contain vasomotor fibres as well as afferent fibres serving pain and proprioception.

Movements

Being a uniaxial joint, the elbow allows flexion and extension, the ulna moving on the trochlea, and the radial head on the capitulum. However, ulnar flexion–extension is not a pure swing but is accompanied by slight conjunct rotation, the ulna being slightly pronated in extension, supinated in flexion. Since the capitulum is smaller than the radial facet, the head of the radius can be felt at the back of the joint in full extension, which is limited by tension in the capsule and muscles anterior to the joint (extension being the close-packed position) and the entry of the tip of the olecranon into the olecranon fossa. Flexion is limited chiefly by apposition of soft parts: in full flexion the rim of the radial head and the tip of the ulnar coronoid process enter the radial and coronoid fossae of the humerus respectively.

When the forearm is fully extended and supinated, it diverges laterally forming with the upper arm a ‘carrying angle’ of approximately 163°; its ulnar border cannot contact the lateral surface of the thigh. The ‘carrying angle’ is caused partly by projection of the medial trochlear edge about 6 mm beyond its lateral edge and partly by the obliquity of the superior articular surface of the coronoid, which is not orthogonal to the shaft of the ulna. Tilt of the humeral and ulnar articular surfaces is approximately equal, hence the carrying angle disappears in full flexion, the two bones reaching the same plane. When the adducted arm is flexed the little finger meets the clavicle, because of the position of the resting humerus; when the humerus is rotated laterally, the hand reaches the front of the shoulder. The carrying angle is also masked by pronation of the extended forearm, which brings the upper arm, semipronated forearm and hand into line, increasing manual precision in full extension of the elbow or during extension.

Accessory movements
These are limited to slight ulnar screwing, abduction and adduction, and anteroposterior translation of the radial head on the capitulum. In translation the radial head moves on the ulnar radial notch and the anular ligaments are slewed backwards and forwards, more so when the elbow is semiflexed.

Muscles producing movement

Flexion: brachialis, biceps brachii and brachioradialis. In slow flexion or its maintenance against gravity, brachialis and biceps are principally involved, even for light loads. With increasing speed, activity in brachioradialis is increasingly prominent; its attachments determine that it acts most effectively in midpronation. Against resistance, pronator teres and flexor carpi radialis may also act.

Extension: triceps, anconeus and gravity. In rapid extension, brachioradialis may be active.

Relations

Muscles related to the joint are: brachialis (anteriorly), triceps and anconeus (posteriorly), supinator and the common extensor tendon (laterally), and the common flexor tendon and flexor carpi ulnaris (medially).
PROXIMAL (SUPERIOR) RADIO-ULNAR JOINT

The proximal radio-ulnar joint is a uniaxial pivot joint.

Articulating surfaces

The articulating surfaces are between the circumference of the radial head and the fibro-osseous ring made by the ulnar radial notch and anular ligament.

Fibrous capsule

The capsule is continuous with that of the elbow joint and is attached to the anular ligament.

Ligaments

The proximal radio-ulnar joint has anular and quadrate ligaments.

Anular ligament

This is a strong band, which encircles the radial head, holding it against the radial notch of the ulna. Forming about four-fifths of the ring, it is attached to the anterior margin of the notch, broadens posteriorly and may divide into several bands. It is attached to a rough ridge at or behind the posterior margin of the notch; diverging bands may also reach the lateral margin of the trochlear notch above and proximal end of the supinator crest below. The proximal anular border blends with the elbow joint capsule, except posteriorly where the capsule passes deep to the ligament to reach the posterior and inferior margins of the radial notch. From the distal anular border a few fibres pass over reflected synovial membrane to attach loosely on the radial neck. The external surface of the anular ligament blends with the radial collateral ligament and provides an attachment for part of supinator. Posterior to it are anconeus and the interosseous recurrent artery. Internally the ligament is thinly covered by cartilage where it is in contact with the radial head; distally it is covered by synovial membrane, reflected up onto the radial neck.

Quadrate ligament

This thin, fibrous ligament stretches between the neck of the radius and the upper part of the supinator fossa of the ulna and covers the synovial membrane on the distal surface of the joint. It maintains constant tension throughout pronation and supination.

Synovial membrane

The synovial membrane is continuous with that of the elbow joint so that the proximal radio-ulnar joint and elbow joint form one continuous synovial cavity.
It is attached to the articular margins and lines the capsule and anular ligament. It is prevented from herniation between the anterior and posterior free edges of the anular ligament by the quadrate ligament.

**Vascular supply**

Articular arteries are derived from the numerous periarticular anastomoses (Fig. 47.6).

**Innervation**

Innervation is by small branches from the musculocutaneous, median, radial and ulnar nerves.

**Factors maintaining stability**

The prime stabilizing factor (Fig. 48.2, Fig. 48.3) is the anular ligament which encircles the radial head and holds it against the radial notch of the ulna.

**Movements and muscles producing movement**

See the description of the distal radio-ulnar joint (p. 468).

**Injuries around the elbow**

Posterior dislocation of the elbow joint with ulnar abduction can be complicated by fracture of the coronoid process as it impinges against the trochlea of the humerus. The normal triangular relationship between the olecranon and the two humeral epicondyles is disrupted. The brachial artery and/or median and ulnar nerves can occasionally be damaged in these injuries. The strength of the collateral ligaments is such that the medial epicondyle is frequently torn off in lateral dislocations.

Subluxation of the radial head through the anular ligament arising from a sudden jerk on the arm is a relatively common injury in young children (known as 'pulled elbow'). This is because the anular ligament has vertical sides in children compared with more funnel-shaped sides in adults. Reduction involves forcefully supinating and flexing the elbow which snaps the ligament back into place.

Supracondylar distal humeral fractures are usually seen in children following a fall on the outstretched hand. The distal fragment in usually displaced posteriorly. The jagged end of the proximal fragment can sometimes injure the brachial artery or the median nerve.
DISTAL (INFERIOR) RADIO-ULNAR JOINT

Movements at the radio-ulnar joint complex pronate and supinate the hand. The distal radio-ulnar joint and the movements which occur during supination and pronation are described on page 468.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIES

Brachial artery

The brachial artery is central and divides near the neck of the radius into its terminal branches, namely the radial and ulnar arteries (Fig. 48.1, Fig. 48.6). The skin, superficial fascia and median cubital vein are anterior, separated by the bicipital aponeurosis. Posteriorly, brachialis separates it from the elbow joint. The median nerve is medial proximally but is separated from the ulnar artery by the ulnar head of pronator teres. Lateral are the tendon of biceps and the radial nerve, the latter concealed between supinator and brachioradialis.
Radial artery

The radial artery passes deep to brachioradialis and gives off the radial recurrent artery before continuing into the forearm (Fig. 48.1, Fig. 48.6).

Radial recurrent artery

The radial recurrent artery (Fig. 47.6, Fig. 48.6) arises just distal to the elbow,
passing between superficial and deep branches of the radial nerve to ascend behind brachioradialis, anterior to supinator and brachialis. It supplies these muscles and the elbow joint, anastomosing with the radial collateral branch of the profunda brachii.

**Ulnar artery**

The ulnar artery gives off the anterior and then the posterior ulnar recurrent arteries before passing deep to pronator teres to continue its course in the forearm (Fig. 48.1, Fig. 48.6). In the forearm, the posterior interosseous artery (a branch of the ulnar artery via the common interosseous artery), gives rise to the posterior interosseous recurrent artery which passes proximally to supply the elbow region.

The common interosseous, anterior interosseous and posterior interosseous arteries, and muscular branches of the ulnar artery, are described on p. 852.

**Anterior ulnar recurrent artery**

The anterior ulnar recurrent artery (Fig. 47.6) arises just distal to the elbow, ascends between brachialis and pronator teres, supplies them and anastomoses with the inferior ulnar collateral artery anterior to the medial epicondyle.

**Posterior ulnar recurrent artery**

The posterior ulnar recurrent artery (Fig. 47.6) arises distal to the anterior ulnar recurrent, and passes dorsomedially between flexors digitorum profundus and superficialis, ascending behind the medial epicondyle; between this and the olecranon, it is deep to flexor carpi ulnaris, ascending between its heads with the ulnar nerve. It supplies adjacent muscles, nerve, bone and elbow joint, and anastomoses with the ulnar collateral and interosseous recurrent arteries (Fig. 47.6).

**Posterior interosseous recurrent artery**

The posterior interosseous recurrent artery is a branch of the posterior interosseous artery. It passes proximally through supinator to lie deep to anconeus posterior to the lateral epicondyle. It gives off branches which take part in the anastomotic cutaneous plexus around the olecranon.
VEINS

The deep and superficial veins supplying the elbow and related structures are described on page 853. Fig. 48.7 shows the common variants of the superficial veins of the cubital fossa: their easy access means that the cubital veins are common sites for venous blood puncture and intravenous fluid and drug administration.

Fig. 48.7 A–C, Variations of superficial veins of the left cubital fossa.
(From Sobotta 2006.)
LYMPHATIC DRAINAGE: SUPRATROCHLEAR NODES

One or two supratrochlear nodes (Fig. 45.6) are superficial to the deep fascia proximal to the medial epicondyle and medial to the basilic vein; their efferents accompany the vein to join the deep lymph vessels.

Small isolated nodes sometimes occur along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, or in the arm medial to the brachial vessels.
INNERVATION

Median nerve

In the cubital fossa the median nerve lies medial to the brachial artery, deep to the bicipital aponeurosis and anterior to brachialis (Fig. 48.1, Fig. 48.6).

Pronator syndrome

This is an uncommon entrapment neuropathy of the median nerve occurring in the elbow region. Entrapment can occur typically at four sites. The first occurs at the site of the ligament of Struthers. This ligament represents an anatomical variant and when present connects a small supracondylar spur of bone to an accessory origin of pronator teres. The median nerve can be compressed as it passes under this ligament. The nerve may also be trapped as it passes deep to the bicipital aponeurosis; the aponeurotic edge of the deep head of pronator teres muscle; or the tendinous aponeurotic arch forming the proximal free edge of the radial attachment of flexor digitorum superficialis.

The syndrome presents with pain on the volar aspect of the distal arm and proximal forearm. The symptoms may be aggravated by flexing the elbow against resistance, pronating the forearm against resistance, or flexion of superficialis to the middle finger against resistance, depending on the precise cause of the entrapment. If the anterior interosseous nerve is also compressed there is weakness of all the muscles innervated by the median nerve, including abductor pollicis brevis and the long finger flexors, and sensory impairment on the palm of the hand. Treatment involves exploration of the nerve and surgical decompression.

Musculocutaneous nerve

In the cubital fossa the musculocutaneous nerve lies at the lateral margin of the biceps tendon where it continues on as the lateral cutaneous nerve of the forearm.

Ulnar nerve

At the elbow the ulnar nerve is in a groove on the dorsum of the medial epicondyle. It enters the forearm between the two heads of flexor carpi ulnaris superficial to the posterior and oblique parts of the ulnar collateral ligament (Fig. 48.6, Fig. 48.8, Fig. 48.9).
Fig. 48.8  Posterior aspect of the left elbow, superficial structures.
Articular branches to the elbow joint arise from the ulnar nerve between the medial epicondyle and olecranon.

Cubital tunnel syndrome
Typically the ulnar nerve can be compressed in the tunnel formed by the tendinous arch connecting the two heads of flexor carpi ulnaris at their humeral and ulnar attachments. Other local causes of compression and neuritis at this site include trauma, inflammatory arthritis, compression by the medial head of the triceps, osteophytes, recurrent subluxation of the nerve across the medial epicondyle of the humerus and abnormal muscular variants such as the anconeus epitrochlearis.

The symptoms are pain at the medial aspect of the proximal forearm together with paraesthesia and numbness of the little finger and ulnar half of the ring finger and the ulnar side of the dorsum of the hand. These symptoms are typically worse on forced elbow flexion. There may also be associated weakness of the muscles of the forearm and the intrinsic muscles of the hand innervated by the ulnar nerve. Interestingly, flexor carpi ulnaris and profundus to the ring and little fingers are frequently spared, presumably because the fascicles supplying these muscles are located on the deep aspect of the nerve. Clawing of the hand is therefore unusual in this syndrome.

Surgical treatment involves decompression of the tunnel by division of the aponeurosis of flexor carpi ulnaris with or without subsequent anterior transposition of the ulnar nerve.

Ulnar nerve division at the elbow

– The ulnar nerve is in a vulnerable position as it lies between the medial epicondyle and the olecranon: it lies on bone covered only by a thin layer of skin. It is easily damaged if the ulnar groove is shallow and the nerve may become more prominent than the medial epicondyle or the olecranon when the elbow is fully flexed.

Division of the nerve at the elbow paralyses flexor carpi ulnaris, flexor digitorum profundus to the ring and little fingers and all the intrinsic muscles of the hand (apart from the radial two lumbricals). The clawing of the hand is less intense than occurs after division of the ulnar nerve at the wrist, reflecting the imbalance in action between the long flexors and extensors to the ring and little fingers when finger flexion is produced only by superficialis. In addition there is sensory loss over the little finger and the ulnar half of the ring finger.

Radial nerve

The radial nerve at the elbow lies deep in a groove between brachialis and brachioradialis proximally and extensor carpi radialis distally. It divides into the superficial terminal branch and the posterior interosseous nerve just anterior to the lateral epicondyle (Fig. 48.6).

Articular branches are distributed to the elbow joint.
Medial and posterior cutaneous nerves of the forearm

The medial cutaneous nerve is described on pages 830 and 856, and the posterior cutaneous nerve is described on pages 829 and 856.

CHAPTER 49 – Forearm

SKIN AND SOFT TISSUE

SKIN

Cutaneous vascular supply

Fasciocutaneous perforators from the radial artery supply the lateral two-thirds of the anterior surface of the forearm, the lateral (radial) border and the posterior one-quarter of the forearm (except in the distal third) (see Fig. 45.4). These perforators pass in the intermuscular fascia between brachioradialis and flexor carpi radialis and between flexor carpi radialis and flexor digitorum superficialis (see Fig. 49.17). Within the territory of the radial artery is the area of the largest fasciocutaneous perforator, which has recently been named the inferior cubital artery. It extends from the distal apex of the antecubital fossa to midway down the forearm. Fasciocutaneous perforators from the ulnar artery supply an anatomical area which extends from the cubital fossa to the wrist, and from the medial (ulnar) third of the anterior aspect of the forearm around the medial border to the medial one-quarter of the posterior surface of the forearm (see Fig. 49.17, Fig. 45.4).
Very small musculocutaneous perforators pass through brachioradialis and flexor carpi ulnaris. The contribution from these is far less than that of the fasciocutaneous perforators.

The distal third of the lateral (radial) aspect of the forearm is supplied by the terminal perforating branches of the anterior interosseous artery (see Fig. 45.4).

The central half of the posterior surface of the forearm, from the lateral edge of extensor digitorum, just below the lateral epicondyle of the humerus, to the wrist, is supplied by fasciocutaneous perforators which arise from the posterior interosseous artery. They reach the skin by passing along the intermuscular fascia between extensor carpi ulnaris and extensor digit minimi (see Fig. 49.17, Fig. 45.4).

For a detailed account of the cutaneous blood supply to the forearm, see Cormack & Lamberty (1994) and the translated works of Salmon (1994).

**Cutaneous innervation**

The anterior aspect of the forearm is supplied by the anterior branches of the medial and lateral cutaneous nerves of the forearm (see Fig. 45.15). The medial and lateral regions of the posterior aspect of the forearm are supplied by the posterior branches of the medial and lateral cutaneous nerves of the forearm respectively. The central part of the posterior aspect of the forearm is supplied by the posterior cutaneous nerve of the forearm.
SOFT TISSUE

*Interosseous membrane*

The radial and ulnar shafts are connected by syndesmoses – an oblique cord and an interosseous membrane.

**Oblique cord**

The oblique cord is a small inconstant flat fascial band on the deep head of supinator (Fig. 49.1). It extends from the lateral side of the ulnar tuberosity to the radius a little distal to its tuberosity. Its fibres are at right angles to those in the interosseous membrane. Its functional significance is dubious.
**Interosseous membrane**

The interosseous membrane is a broad, thin, collagenous sheet (Fig. 49.1). Its fibres slant distomedially between the radial and ulnar interosseous borders, and its distal part is attached to the posterior division of the radial border. Two or three posterior bands occasionally descend distolaterally across the other fibres. The membrane is deficient proximally, starting 2 or 3 cm distal to the radial tuberosity, and broader at midlevel. An oval aperture near its distal margin conducts the anterior interosseous vessels to the back of the forearm, and the posterior interosseous vessels pass through a gap between its proximal border and the oblique cord.

The membrane provides attachments for the deep forearm muscles and connects the radius and ulna. Its fibres appear to transmit forces which act proximally from the hand to the radius, thence to the ulna and humerus. However the hand is usually pronated when subject to these forces, and the membrane is relaxed in complete pronation and supination: the interosseous membrane is only tense when the hand is midway between prone and supine positions. Moreover, the radius can transmit substantial forces directly to the humerus. Anteriorly, in its proximal three-quarters, the membrane is related laterally to flexor pollicis longus and medially to flexor digitorum profundus, and between them to the anterior interosseous vessels and nerve. In its distal quarter it is related to pronator quadratus. Its posterior relations are supinator, abductor pollicis longus, extensors pollicis brevis, longus and indicis and, near the carpus, the anterior interosseous artery and posterior interosseous nerve.

**Compartments of the forearm**

The antebrachial fascia (deep fascia of the forearm), which is continuous above with the brachial fascia, is a dense general sheath for muscles, collectively and individually, in this region. It is attached to the olecranon and posterior border of the ulna. From its deep surface septa pass between muscles, providing partial attachment for them, and some of these septa reach bone. Muscles also arise from its internal aspect, especially in the upper forearm. This deep fascia, together with the interosseous membrane and fibrous intermuscular septa, divide the forearm into a number of compartments. These are the superficial and deep flexor (anterior) compartments, the extensor (posterior compartment) and a proximolateral compartment known as the mobile wad (encompassing brachioradialis and extensors carpi radialis longus and brevis) (Fig. 49.2). The fascia is much thicker posteriorly and in the lower forearm. It is strengthened above by tendinous fibres from biceps and triceps. Near the wrist, two localized thickenings, the flexor and extensor retinacula, retain the digital tendons in position (p. 879). Vessels and nerves pass through apertures in the fascia. One large aperture anterior to the elbow transmits a venous communication between superficial and deep veins.
Compartment syndrome

The deep fascia in the forearm has limited elasticity and consequently any accumulation of fluid within this space (e.g. from haemorrhage, swelling from trauma, burns) can lead to increased tension in the compartment. If this pressure is high enough (35 mmHg), tissue perfusion pressure will be compromised and this will lead to a compartment syndrome where ischaemia and necrosis of the tissues ensues. Once muscle becomes infarcted the damage is irreversible: muscle fibres become contracted and replaced by inelastic fibrous tissue (termed Volkmann's ischaemic contracture). The symptoms and signs associated with compartment syndrome are pain (particularly on passive stretching of the compartmental muscles), weakness of the compartment muscles, tenseness of the compartment, paraesthesia and hyperaesthesia. The pulse can still be normal in compartment syndrome, because systolic blood pressure is well above the critical closing pressure of vessels which supply the tissues within the compartment.

Compartment syndromes can occur at various sites in the body, but more commonly affect the anterior compartment of the forearm, the intrinsic muscles of the hand, and the lower leg. The identification of a compartment syndrome requires urgent surgical decompression. Here, both the skin and deep fascia are incised throughout the whole length of the compartment to relieve the pressure.
The radius is the lateral bone of the forearm (Fig. 49.3, Fig. 49.4, Fig. 49.5). It has expanded proximal and distal ends; the distal is much the broader. The shaft widens rapidly towards its distal end, is convex laterally and concave anteriorly in its distal part.

Fig. 49.4 Articulated radius and ulna: posterior view showing muscle attachments. 1. Triceps. 2. Biceps. 3. Supinator. 4. Abductor pollicis longus. 5. Pronator teres. 6. Extensor pollicis brevis. 7. Subcutaneous area. 8. Anconeus. 9. Posterior border: attachment for common aponeurosis of extensor carpi ulnaris, flexor carpi ulnaris, flexor digitorum profundus. 10. Extensor pollicis longus. 11. Extensor indicis.
The proximal end includes a head, neck and tuberosity. The head is discoid, its proximal surface a shallow cup for the humeral capitulum. Its smooth articular periphery is vertically deepest medially, where it contacts the ulnar radial notch. Its posterior surface is palpable in a small depression on the lateral side of the back of the extended elbow. The neck is the constriction distal to the head, which overhangs it, especially on the lateral side. The tuberosity is distal to the medial part of the neck; posteriorly it is rough, but anteriorly it is usually smooth.

Shaft

The shaft has a lateral convexity, and is triangular in section (Fig. 49.1). The
The interosseous border is sharp, except for two areas: proximally, near the tuberosity; and distally, where the interosseous border is the posterior margin of a small, elongated, triangular area, proximal to the ulnar notch. These two areas form the so-called medial surface. The interosseous membrane is attached to its distal three-fourths, and connects the radius to the ulna. The anterior border is obvious at both ends, but rounded and indefinite between them. It descends laterally from the anterolateral part of the tuberosity as the anterior oblique line, which distally becomes a sharp, palpable crest along the lateral margin of the anterior surface. The posterior border is well defined only in its middle third: proximally it ascends medially towards the posteroinferior part of the tuberosity, and distally it is merely a rounded ridge. The anterior surface, between anterior and interosseous borders, is concave transversely and shows a distal forward curvature. Near its midpoint there is a proximally directed nutrient foramen and canal. The posterior surface, between interosseous and posterior borders, is largely flat but may be slightly hollow in the proximal area. The lateral surface is gently convex. Proximally, due to the obliquity of the anterior and posterior borders, it encroaches on the anterior and posterior aspects and is here slightly rough. A finely irregular oval area occurs near the midshaft, and beyond it the surface is smooth.

**Distal end**

The distal end of the radius (Fig. 49.6) is the widest part. It is four-sided in section. The lateral surface is slightly rough, projecting distally as a styloid process which is palpable when tendons around it are slack. The smooth carpal articular surface is divided by a ridge into medial and lateral areas. The medial is quadrangular, whereas the lateral is triangular and curves on to the styloid process. The anterior surface is a thick, prominent ridge, palpable even through overlying tendons, 2 cm proximal to the thenar eminence. The medial surface is the ulnar notch, which is smooth and anteroposteriorly concave for articulation with the head of the ulna. The posterior surface displays a palpable dorsal tubercle (Lister's tubercle), which is limited medially by an oblique groove and is in line with the cleft between the index and middle fingers. Lateral to the tubercle there is a wide, shallow groove, divided by a faint vertical ridge.
Muscle, ligament and articular attachments

The proximal articular surface of the radial head and its circumference are covered by hyaline cartilage. The upper rim (margin) fits the groove between the capitulum and trochlea and enters the radial fossa in flexion. The articular circumference articulates with the ulnar radial notch and annular ligament, within which it rotates in pronation and supination. The radial neck is enclosed by the narrower distal part of the ligament, from which it is separated by a synovial protrusion from the superior radio-ulnar joint. The posterior area of the tuberosity is marked by the biceps tendon, which is separated from a smooth anterior area by a bursa. The oblique cord is attached just distal to the bursa.

The thin, wide radial head of flexor digitorum superficialis is attached proximally on the anterior border. The lateral edge of the extensor retinaculum is attached to its conspicuous distal part. A small, triangular area proximal to the ulnar notch gives attachment to the deepest part of pronator quadratus.

The proximal two-thirds of the anterior surface provides an extensive area for attachment of flexor pollicis longus, which conceals the nutrient foramen. Pronator quadratus is attached to the distal quarter, and pronator teres is attached to a rough area near the midpoint of its lateral surface, at its maximal curvature. Proximally, the lateral surface widens into a long V-shaped area for supinator (Fig. 49.3, Fig. 49.4). Distal to pronator teres, the lateral surface is covered by tendons of the radial extensors. On the posterior surface, abductor pollicis longus is attached proximally and, more distally, extensor pollicis brevis. The remaining surface is devoid of attachments and covered by the long and short extensors of the thumb.

The radial styloid process projects beyond that of the ulna, its apex concealed by the tendons of abductor pollicis longus and extensor pollicis brevis. The lateral radiocarpal ligament is attached to its tip. The lateral surface, near the styloid process, receives the attachment of brachioradialis and is crossed obliquely, downwards and forwards, by the tendons of abductor pollicis longus and extensor pollicis brevis. The terminal ridge on the anterior surface of the lower end is an attachment for the palmar radiocarpal ligament. The base of the triangular articular disc of the inferior radio-ulnar joint is attached to a smooth ridge distal to the ulnar notch. From the latter, a narrow protrusion of synovial membrane extends proximally anterior to the lower end of the interosseous membrane (p. 839). The lateral part of the carpal articular surface articulates with the scaphoid, and the medial part with the lateral part of the lunate. In
full adduction, the proximal surface of the lunate is wholly in contact with the radius.

The radial dorsal tubercle receives a slip from the extensor retinaculum and is
grooved medially by the tendon of extensor pollicis longus. The wide groove lateral to
the tubercle contains the tendons of extensor carpi radialis longus laterally, and
extensor carpi radialis brevis medially, together with their synovial sheaths. Medially
the dorsal surface is grooved by the tendons of extensor digitorum, which are
separated from the bone by the tendons of extensor indicis and the posterior
interosseous nerve. The dorsal radiocarpal ligament is attached to the distal margin of
this surface.

Vascular supply

There are multiple metaphysial nutrient foramina that transmit branches of the radial,
ulnar, anterior and posterior interosseous arteries. Typically, there is one nutrient
diaphysial foramina located on the anterior surface of the bone and directed
proximally toward the elbow. There is also a network of small fascioperiosteal and
musculoperiosteal vessels which arise from the compartmental vessels and reach the
bone via septal and muscular attachments.

The dorsal metaphysial supply of the distal radius is of particular importance to
reconstructive hand surgeons because of its potential use in raising vascularized
pedicled bone grafts (Fig. 49.7). Consistent branches connecting the anterior
interosseous artery proximally to the dorsal carpal arch distally pass through the fourth
and fifth extensor compartments of the wrist and provide metaphysial nutrient arteries.
Intercompartmental vessels send nutrient arteries to the radius through the
retinaculum between the first and second dorsal compartments, and the second and
third dorsal compartments. These vessels originate from the radial artery and anterior
interosseous arteries respectively, and anastomose with the dorsal carpal arch. For an
anatomical description detailing the practical application of such pedicled bone grafts
Fig. 49.7  A, B, Extraosseous arterial supply to the dorsal distal radius and ulna. C, D, Extraosseous arterial supply to the palmar distal radius and ulna. The shaded regions demonstrate where the nutrient vessels from the labelled arteries penetrate bone.
Ossification

The radius ossifies from three centres. One appears centrally in the shaft in the eighth week of fetal life, and the others appear in each end (Fig. 49.8, Fig. 49.9). Ossification begins in the distal epiphysis towards the end of the first postnatal year, and in the proximal epiphysis during the fourth year in females, and fifth in males. The proximal epiphysis fuses in the 14th year in females, 17th in males, and the distal in the 17th and 19th years respectively. A fourth centre sometimes appears in the tuberosity at about the 14th or 15th year.

Fig. 49.8 A, Stages in the ossification of the radius (not to scale). B, The epiphysial lines of the adolescent left radius, anterior aspect. The attachment of the wrist joint capsule is in blue.
ULNA

The ulna is medial to the radius in the supinated forearm (Fig. 49.3, Fig. 49.4). Its proximal end is a massive hook which is concave forwards (Fig. 49.10). The lateral border of the shaft is a sharp interosseous crest. The bone diminishes progressively from its proximal mass throughout almost its whole length, but at its distal end expands into a small rounded head and styloid process. The shaft is triangular in section but has no appreciable double curve. In its whole length it is slightly convex posteriorly. Mediolaterally, its profile is sinuous. The proximal half has a slight laterally concave curvature, and the distal half a medially concave curvature.

Fig. 49.10 Proximal end of left ulna: lateral view. 1. Olecranon. 2. Non-articular strip in trochlear notch. 3. Coronoid process. 4. Tuberosity. 5. Trochlear notch. 6. Radial notch. 7. Supinator crest. 8. Shaft.
**Proximal end**

The proximal end has large olecranon and coronoid processes and trochlear and radial notches which articulate with the humerus and radius (Fig. 49.10). The olecranon is more proximal and is bent forwards at its summit like a beak, which enters the humeral olecranon fossa in extension. Its posterior surface is smooth, triangular and subcutaneous, and its proximal border underlies the 'point' of the elbow. In extension it can be felt near a line joining the humeral epicondyles, but in flexion it descends, so that the three osseous points form an isosceles triangle. Its base is slightly constricted where it joins the shaft and is the narrowest part of the proximal ulna. The coronoid process projects anteriorly distal to the olecranon. Its proximal aspect forms the distal part of the trochlear notch. On the lateral surface, distal to the trochlear notch, there is a shallow, smooth, oval radial notch which articulates with the radial head. Distal to the radial notch the surface is hollow to accommodate the radial tuberosity during pronation and supination. The anterior surface of the coronoid is triangular. Its distal part is the tuberosity of the ulna. Its medial border is sharp and bears a small tubercle proximally.

The trochlear notch articulates with the trochlea of the humerus. It is constricted at the junction of the olecranon and coronoid processes, where their articular surfaces may be separated by a narrow rough non-articular strip. A smooth ridge, adapted to the groove on the humeral trochlea, divides the notch into medial and lateral parts. The medial fits into the trochlear flange. The radial notch, an oval or oblong proximal depression on the lateral aspect of the coronoid process, articulates with the periphery of the radial head, and is separated from the trochlear notch by a smooth ridge (Fig. 49.10).

**Shaft**

The shaft is triangular in section in its proximal three-fourths, but distally is almost cylindrical (Fig. 49.3, Fig. 49.4). It has anterior, posterior and medial surfaces and interosseous, posterior and anterior borders. The interosseous border is a conspicuous lateral crest in its middle two-fourths. Proximally it becomes the supinator crest, which is continuous with the posterior border of a depression distal to the radial notch. Distally, it disappears. The rounded anterior border starts medial to the ulnar tuberosity, descends backwards, and is usually traceable to the base of the styloid process. The posterior border, also rounded, descends from the apex of the posterior aspect of the olecranon, and curves laterally to reach the styloid process. It is palpable throughout its length in a longitudinal furrow which is most obvious when the elbow is fully flexed.

The anterior surface, between the interosseous and anterior borders, is longitudinally grooved, sometimes deeply (Fig. 49.3). Proximal to its midpoint there is a nutrient foramen, which is directed proximally and contains a branch of the anterior interosseous artery. Distally, it is crossed obliquely by a rough, variable prominence, descending from the interosseous to the anterior border. The medial surface, between the anterior and posterior borders, is transversely convex and smooth. The posterior surface, between the posterior and interosseous borders, is divided into three areas (Fig. 49.4). The most proximal is limited by a sometimes faint oblique line ascending laterally from the junction of the middle and upper thirds of the posterior border to the
posterior end of the radial notch. The region distal to this line is divided into a larger medial and narrower lateral strip by a vertical ridge, usually distinct only in its proximal three-fourths.

**Distal end**

The distal end is slightly expanded and has a head and styloid process. The head is visible in pronation on the posteromedial carpal aspect, and can be gripped when the supinated hand is flexed. Its lateral convex articular surface fits the radial ulnar notch. Its smooth distal surface (Fig. 49.6) is separated from the carpus by an articular disc, the apex of which is attached to a rough area between the articular surface and styloid process. The latter, a short, round, posterolateral projection of the distal end of the ulna, is palpable (most readily in supination) about 1 cm proximal to the plane of the radial styloid. A posterior vertical groove is present between the head and styloid process.

**Muscle, ligament and articular attachments**

Anteriorly, the capsule of the elbow joint is attached to the proximal olecranon surface. The tendon of triceps is attached to its rough posterior two-thirds: the capsule and tendon can be separated by a bursa. The medial surface of the olecranon is marked proximally by the attachment of the posterior and oblique bands of the ulnar collateral ligament and the ulnar part of flexor carpi ulnaris. The smooth area distal to this is the most proximal attachment of flexor digitorum profundus. Anconeus is attached to the lateral olecranon surface and the adjoining posterior surface of the ulnar shaft as far as its oblique line. The posterior surface of the ulna is separated from the skin by a subcutaneous bursa.

Brachialis is attached to the anterior surface of the coronoid process, including the ulnar tuberosity. The oblique and anterior bands of the ulnar collateral ligament and the distal part of the humero-ulnar slip of flexor digitorum superficialis are attached to a small tubercle at the proximal end of the medial border. Distal to this the margin provides attachment for the ulnar part of pronator teres. An ulnar part of flexor pollicis longus may be attached to the lateral or, more rarely, the medial border of the coronoid process. Fibres of flexor digitorum profundus are attached to its medial surface. The annular ligament is attached to the anterior rim of the radial notch and posteriorly to a ridge at or just behind the posterior margin of the notch. The depressed area distal to the notch is limited behind by the supinator crest, and both provide attachment for supinator.

The olecranon area of the trochlear notch is usually divided into three areas. The most medial faces anteromedially, and is grooved to fit the medial flange of the humeral trochlea, with which it makes increasing contact during flexion. A flat intermediate area fits the lateral flange, and the most lateral area, a narrow strip, abuts the trochlea in extension. The articular surface is narrower than the base of the olecranon: non-articular parts are related to the synovial processes. The coronoid area of the trochlear notch is also divided, and its medial and lateral areas correspond to medial and intermediate areas of the olecranon. The medial is more hollow, and conforms to the convex medial trochlear flange. The medial and anterior parts of the capsular ligament are attached to its medial and anterior borders.

The deep fascia of the forearm is attached to the subcutaneous posterior border. This
border also provides an attachment for the aponeurosis of flexor digitorum profundus in its proximal three-quarters, for flexor carpi ulnaris in its proximal half, and for extensor carpi ulnaris in its middle third. These three muscles connect with the posterior border through a common blended aponeurosis. The interosseous membrane is attached to the interosseous border, except proximally.

Flexor digitorum profundus is attached to the proximal three-fourths of the anterior border and medial surface, attaching medial to the coronoid process and olecranon. The rough strip across the distal fourth of the anterior surface provides part of the bony attachment for pronator quadratus. Anconeus is attached to the posterior surface proximal to the oblique line and lateral to the olecranon. The narrow strip between the interosseous border and vertical ridge gives rise to the attachment of three deep muscles: abductor pollicis longus arises from the proximal fourth, extensor pollicis longus arises from the succeeding fourth (sometimes a ridge is interposed between them), and extensor indicis is attached to the third quarter. The broad strip medial to the vertical ridge is covered by extensor carpi ulnaris, whose tendon grooves the posterior aspect of the distal end of the ulna. The ulnar collateral ligament is attached to the apex of the styloid process.

Vascular supply

Multiple metaphysial nutrient foramina transmit branches of the radial, ulnar, anterior and posterior interosseous arteries (Fig. 49.7). These vessels give off a number of smaller segmental branches. Usually one, but occasionally two, major nutrient diaphysial foramina are located on the anterior surface of the bone, directed proximally toward the elbow. A network of small fascioperiosteal and musculoperiosteal branches given off from the compartmental vessels reaches the bone via septal and muscular attachments.

Ossification

The ulna ossifies from four main centres, one each in the shaft and distal end and two in the olecranon (Fig. 49.11). Ossification begins in the midshaft about the eighth fetal week, and extends rapidly. In the fifth (females) and sixth (males) years, a centre appears in the distal end, and extends into the styloid process. The distal olecranon is ossified as an extension from the shaft, the remainder from two centres, one for the proximal trochlear surface, and the other for a thin scale-like proximal epiphysis on its summit. The latter appears in the ninth year in females, 11th in males. The whole proximal epiphysis has joined the shaft by the 14th year in females, sixteenth in males. The distal epiphysis unites with the shaft in the 17th year in females, 18th in males.
Fig. 49.11  A. Stages in the ossification of the ulna. The diagram is simplified in relation to the ossification of the olecranon epiphysis, which is said to have two centres. B. The epiphysial lines of the adolescent left ulna, lateral aspect. The attachment of the joint capsules is in blue.
MUSCLES

ANTERIOR COMPARTMENT

The anterior compartment contains the flexor muscles of the forearm which are arranged in superficial and deep groups. Chronic tendonitis of the common flexor tendon origin produces medial epicondyliitis of the elbow, leading to pain and tenderness. It is a frequent complaint among golfers. A detailed account of the architectural properties of the muscles of the arm and forearm is given by Leiber et al (1992).

Superficial flexor compartment

Muscles of the superficial flexor compartment arise from the medial epicondyle of the humerus by a common tendon. They are pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum superficialis, and flexor carpi ulnaris (Fig. 49.12). They have additional attachments to the antebrachial fascia near the elbow and to the septa that pass from this fascia between individual muscles.
Fig. 49.12 The superficial flexor muscles of the left forearm.  
(From Sobotta 2006.)

**Pronator teres**

**Attachments**

Pronator teres has humeral and ulna attachments (Fig. 49.3, Fig. 49.12, Fig. 49.13). The humeral head, the larger and more superficial of the two, arises
just proximal to the medial epicondyle, from the common tendon of origin of the flexor muscles, from the intermuscular septum between it and flexor carpi radialis, and from antebrachial fascia. The smaller ulnar head springs from the medial side of the coronoid process of the ulna, distal to the attachment of flexor digitorum superficialis, and joins the humeral head at an acute angle. The muscle passes obliquely across the forearm to end in a flat tendon that is attached to a rough area midway along the lateral surface of the radial shaft at the ‘summit’ of its lateral curve. The coronoid attachment may be absent. Accessory slips may arise from a supracondylar process of the humerus, if it is present, or from biceps, brachialis or the medial intermuscular septum.
Relations

The median nerve usually enters the forearm between the two heads of pronator teres, and is separated from the ulnar artery by the ulnar head. The lateral border of pronator teres is the medial limit of the cubital fossa, the triangular hollow anterior to the elbow joint.

Vascular supply

The humeral head of pronator teres is supplied by the inferior ulnar collateral artery and the anterior ulnar recurrent artery. The ulnar head is supplied by the common interosseous artery. The mid portion of the muscle belly is supplied by direct branches from the ulnar artery, while the attachment to the radius is supplied by the radial artery.

Innervation

Pronator teres is innervated by the median nerve, C6 and 7.

Action

Pronator teres rotates the radius on the ulna (pronation of the forearm), turning the palm medially so that it faces backwards. It acts with pronator quadratus (which is always active in pronation) only in rapid or forcible pronation. Like all of the muscles which arise from the medial epicondyle, pronator teres acts as a weak flexor of the elbow joint.

Clinical anatomy: testing

Pronator teres is tested by palpating its contracting fibres during pronation against resistance.

*Flexor carpi radialis*

Attachments

Flexor carpi radialis lies medial to pronator teres, and arises from the medial epicondylic via the common flexor tendon, from the antebrachial fascia and from adjacent intermuscular septa (Fig. 49.12). Its fusiform belly ends, rather more than halfway to the wrist, in a long tendon which passes within a synovial sheath through a lateral canal, formed by the flexor retinaculum above and a groove on the trapezium beneath. It inserts on the palmar surface of the base of the second metacarpal, sending a slip to the third
metacarpal. These distal attachments are hidden by the oblique head of adductor pollicis. The muscle rarely may be absent. It may have accessory slips from the biceps tendon, bicipital aponeurosis, coronoid process or radius. Distally it may also be attached to the flexor retinaculum, trapezium or fourth metacarpal.

**Relations**

In the lower part of the forearm the radial artery lies between the tendon of flexor carpi radialis and that of brachioradialis. The surface groove for the radial pulse is well known to all physicians.

**Vascular supply**

Flexor carpi radialis is supplied by a single dominant proximal pedicle and several distal minor pedicles. The dominant pedicle is formed by a branch which arises from either the anterior or posterior ulnar recurrent artery. The latter passes deep to pronator teres to enter the deep surface of flexor carpi radialis, whereupon it divides into a small ascending branch and a larger descending branch. The distal minor pedicles amount to six to eight branches from the radial artery which enter the muscle on the anterolateral side.

**Innervation**

Flexor carpi radialis is innervated by the median nerve, C6 and 7.

**Action**

Acting with flexor carpi ulnaris, and sometimes flexor digitorum superficialis, flexor carpi radialis flexes the wrist, and helps radial extensors of the wrist in abducting the hand.

**Clinical anatomy: testing**

Flexor carpi radialis is tested by palpating its contracting fibres during flexion of the wrist against resistance.

*Flexor digitorum superficialis*

**Attachments**

Flexor digitorum superficialis (sublimis) lies deep to the preceding muscles (Fig. 49.12). It is the largest of the superficial flexors, and arises by two heads. The humero-ulnar head arises from the medial epicondyle of the humerus via the common tendon; the anterior band of the ulnar collateral ligament; adjacent intermuscular septa, and from the medial side of the coronoid process proximal to the ulnar origin of pronator teres. The radial head, a thin sheet of muscle, arises from the anterior radial border extending
from the radial tuberosity to the insertion of pronator teres. The median nerve and ulnar artery descend between the heads. The muscle usually separates into two strata, directed to digits 2–5. The superficial stratum, joined laterally by the radial head, divides into two tendons for the middle and ring finger. The deep stratum gives off a muscular slip to join the superficial fibres directed to the ring finger, and then ends in two tendons for the index and little finger. As the tendons pass behind the flexor retinaculum they are arranged in pairs: the superficial pair pass to the middle and ring fingers, the deep to the index and little finger. Distal to the carpal tunnel the four tendons diverge. Each passes towards a finger superficial to the corresponding flexor digitorum profundus tendon. The two tendons for each finger enter the digital flexor sheath (which starts over the metacarpophalangeal joint) in this relationship. The superficialis tendon then splits into two bundles which pass around the profundus to lie posteriorly. They subsequently reunite and insert into the anterior surface of the middle phalanx. Some fibres interchange from one bundle to another.

An intermediate tendon is always found in the central branching area of the muscle belly and is an important landmark in deep dissection: it can initially be confused with the median nerve. The radial head of flexor digitorum superficialis may be absent and the muscular slip from the deep stratum may provide most or all of the fibres acting on the index finger. The fibres associated with the little finger may be absent, when they are replaced by a separate slip from the ulna, flexor retinaculum or palmar fascia. Variations occur in the arrangement of the tendons.

Relations

The median nerve and ulnar artery descend between the heads of flexor digitorum superficialis.

Vascular supply

The humeral head of flexor digitorum superficialis is supplied by the anterior ulnar recurrent artery. The main part of the muscle is supplied on its anterior surface by three or four branches from both the ulnar and radial arteries. The posterior surface is supplied by the ulnar artery and median artery, and the lateral surface by additional branches from the radial artery.

Innervation

Flexor digitorum superficialis is innervated by the median nerve, C8 and T1.

Action

Flexor digitorum superficialis is potentially a flexor of all the joints over which it passes, i.e. proximal interphalangeal, metacarpophalangeal and wrist
joints. Its precise action depends on which other muscles are acting. It has independent muscle slips to all four fingers, unlike flexor digitorum profundus, which has a muscle group common to the middle, ring and little fingers. It is therefore able to flex the proximal interphalangeal joints individually.

Clinical anatomy: testing

The independent action of flexor digitorum superficialis for a particular finger is tested by flexing that digit while holding the three other fingers in full extension. This eliminates any simultaneous contraction of the flexor digitorum profundus which might flex the digit.

*Palmaris longus*

Attachments

Palmaris longus is a slender, fusiform muscle medial to flexor carpi radialis (Fig. 49.12). It springs from the medial epicondyle by the common tendon, and from adjacent intermuscular septa and deep fascia. It converges on a long tendon, which passes anterior (superficial) to the flexor retinaculum. A few fibres leave the tendon and interweave with the transverse fibres of the retinaculum, but most of the tendon passes distally. As the tendon crosses the retinaculum it broadens out to become a flat sheet which becomes incorporated into the palmar aponeurosis. Palmaris longus is often absent on one or both sides.

Relations

The median nerve at the wrist lies partly under the cover of the tendon of palmaris longus, and partly between the tendons of palmaris longus and flexor carpi radialis.

Vascular supply

The muscle belly of palmaris longus is supplied by a small branch from the anterior ulnar recurrent artery. A small contribution is sometimes made by the median artery, if this is well developed.

Innervation

Palmaris longus is innervated by the median nerve, C7 and 8.

Action

It has been suggested that palmaris longus is a phylogenetically degenerate metacarpophalangeal joint flexor. Although consideration of the line of action would suggest that it plays a role in carpal flexion, its main function appears to be as an anchor for the skin and fascia of the hand, in resisting horizontal
shearing forces in a distal direction (e.g. as in holding a golf club), which would tend to deglove the skin of the palm.

Clinical anatomy: testing

If the wrist is flexed against resistance, the taut tendon of palmaris longus will be seen in the midline of the flexor wrist crease as the tendon passes superficial to the flexor retinaculum. When testing palmaris longus it helps to oppose the thumb to the middle fingertip at the same time as the wrist is flexed in order to make palmaris stand out.

*Flexor carpi ulnaris*

**Attachments**

Flexor carpi ulnaris is the most medial of the superficial forearm flexors (Fig. 49.12). It arises by two heads, humeral and ulnar, connected by a tendinous arch. The small humeral head arises from the medial epicondyle via the common tendon. The ulnar head has an extensive origin from the medial margin of the olecranon and proximal two-thirds of the posterior border of the ulna, an aponeurosis (which it shares with extensor carpi ulnaris and flexor digitorum profundus), and from the intermuscular septum between it and flexor digitorum superficialis. Occasionally there is a slip from the coronoid process. A thick tendon forms along its anterolateral border in its distal half. The tendon is attached to the pisiform, and thence prolonged to the hamate and fifth metacarpal by pisohamate and pisometacarpal ligaments. The attachment to the flexor retinaculum and the fourth or fifth metacarpal bones is sometimes substantial.

**Relations**

The ulnar nerve and posterior ulnar recurrent artery pass under the tendinous arch between the humeral and ulnar heads of flexor carpi ulnaris. Ulnar vessels and nerve lie lateral to the tendon of insertion.

**Vascular supply**

The main arterial supply of flexor carpi ulnaris is derived from three pedicles. The proximal pedicle arises from a branch of the posterior ulnar recurrent artery as it passes between the humeral and ulnar heads. The middle and distal pedicles arise from the ulnar artery and enter the muscle at the junction of the upper and middle thirds, and the musculotendinous junctions, respectively. Flexor carpi ulnaris also receives a small supply near its origin which arises from the inferior ulnar collateral artery.

**Innervation**

Flexor carpi ulnaris is innervated by the ulnar nerve, C7 and 8 and T1.
**Action**

Acting with flexor carpi radialis, flexor carpi ulnaris flexes the wrist. Acting with extensor carpi ulnaris, it adducts (ulnar deviates) the hand.

**Clinical anatomy: testing**

Flexor carpi ulnaris is tested by palpating its fibres while the wrist is flexed against resistance. A more positive test is to palpate the tendon while the patient abducts the little finger against resistance. FCU synergistically contracts to stabilize the pisiform, giving abducted digiti minimi a stable origin.

**Deep flexor compartment**

The muscles of the deep flexor compartment are flexor digitorum profundus, flexor pollicis longus and pronator quadratus.

*Flexor digitorum profundus*

**Attachments**

Flexor digitorum profundus arises deep to the superficial flexors from about the upper three-quarters of the anterior and medial surfaces of the ulna (Fig. 49.13, see Fig. 49.19). It embraces the attachment of brachialis above and extends distally almost to pronator quadratus. It also arises from a depression on the medial side of the coronoid process, the upper three-quarters of the posterior ulnar border (by an aponeurosis which it shares with flexor and extensor carpi ulnaris), and the anterior surface of the ulnar half of the interosseous membrane. The muscle ends in four tendons, which run initially posterior (deep) to the tendons of flexor digitorum superficialis and the flexor retinaculum. The part of the flexor digitorum profundus muscle which acts on the index finger is usually distinct throughout. The tendons for the other fingers are interconnected by areolar tissue and tendinous slips as far as the palm. Anterior to their proximal phalanges, the tendons pass through the tendons of flexor digitorum superficialis to insert on the palmar surfaces of the bases of the distal phalanges. The tendons of the profundus undergo fascicular rearrangement as they pass through those of superficialis.
Flexor digitorum profundus may be joined by accessory slips from the radius (which act on the index finger), flexor superficialis, flexor pollicis longus, the medial epicondyle or the coronoid process.

Relations
Flexor digitorum profundus forms most of the surface elevation medial to the palpable posterior ulnar border. In the palm, the lumbrical muscles are attached to its tendons.

Vascular supply

The origin of flexor digitorum profundus is supplied by the inferior ulnar collateral and ulnar recurrent arteries. The proximal part is supplied by one or two branches from either the ulnar or common interosseous arteries. The distal part is supplied by a series of branches from the ulnar artery, the anterior interosseous artery and the median artery.

Innervation

The medial part of flexor digitorum profundus, i.e. the muscle bellies to the little and ring fingers, is innervated by the ulnar nerve. The lateral part, i.e. the muscle bellies to the middle and index fingers, is innervated by the anterior interosseous branch of the median nerve, C8 and T1.

Action

Flexor digitorum profundus is capable of flexing any or all of the joints over which it passes. It therefore has a role in coordinated finger flexion, but it is the only muscle capable of flexing the distal interphalangeal joints. The index finger tendon is usually capable of independent function, whereas the other three work together. Electromyographically flexor digitorum profundus acts alone in gentle digital flexion and is reinforced by superficialis for greater force and/or velocity.

Clinical anatomy: testing

Flexor digitorum profundus is tested by flexing the distal interphalangeal joint while holding the proximal interphalangeal joint in extension.

Flexor pollicis longus

Attachments

Flexor pollicis longus is lateral to flexor digitorum profundus (Fig. 49.13). It arises from the grooved anterior surface of the radius, and extends from below its tuberosity to the upper attachment of pronator quadratus. It also arises from the adjacent interosseous membrane, and frequently by a variable slip from the lateral, or more rarely medial, border of the coronoid process, or from the medial epicondyle of the humerus. The muscle ends in a flattened tendon, which passes behind the flexor retinaculum, between opponens pollicis and the oblique head of adductor pollicis, to enter a synovial sheath. It inserts on the palmar surface of the base of the distal phalanx of the thumb.
Flexor pollicis longus is sometimes connected to flexor digitorum superficialis, or profundus, or pronator teres. The interosseous attachment, and indeed the whole muscle, may be absent. Anomalous tendon slips from the flexor pollicis longus to the flexor digitorum profundus are common.

Relations

The anterior interosseous nerve and vessels descend on the interosseous membrane between flexor pollicis longus and flexor digitorum profundus.

Vascular supply

The medial half of flexor pollicis longus is supplied by the anterior interosseous artery, while the lateral half is supplied by branches of the radial artery. The median artery may contribute if it is well developed.

Innervation

Flexor pollicis longus is innervated by the anterior interosseous branch of the median nerve, C7 and 8.

Action

Flexor pollicis longus flexes the phalanges of the thumb and the carpometacarpal joint of the thumb, especially if the more distal joints are stiff or fused.

Clinical anatomy: testing

Flexor pollicis longus is tested by flexing the interphalangeal joint of the thumb against resistance.

Pronator quadratus

Attachments

Pronator quadratus is a flat, quadrilateral muscle which extends across the front of the distal parts of the radius and ulna (Fig. 49.13, see Fig. 49.19). It arises from the oblique ridge on the anterior surface of the shaft of the ulna, the medial part of this surface, and a strong aponeurosis which covers the medial third of the muscle. The fibres pass laterally and slightly downwards to the distal quarter of the anterior border and surface of the shaft of the radius. Deeper fibres insert into the triangular area above the ulnar notch of the radius.

Vascular supply

Pronator quadratus receives its main arterial supply from the anterior
interosseous artery as it passes through the interosseous membrane.

Innervation

Pronator quadratus is innervated by the anterior interosseous branch of the median nerve, C7 and 8.

Action

Pronator quadratus is the principal pronator of the forearm, and is assisted by pronator teres only in rapid or forceful pronation. The deeper fibres oppose separation of the distal ends of the radius and ulna when upward thrusts are transmitted through the carpus.

Clinical anatomy: testing

Pronator quadratus is tested by pronation of the forearm against resistance while the wrist finger flexors are relaxed. The simultaneous contraction of pronator teres makes it difficult to test the independent action of pronator quadratus.
POSTERIOR COMPARTMENT

The posterior compartment contains the extensor muscles of the forearm and brachioradialis and supinator. Chronic tendonitis of the common extensor tendon origin produces lateral epicondylitis of the elbow leading to pain and tenderness. It is a frequent complaint among tennis players.

**Superficial extensor compartment**

Brachioradialis

**Attachments**

Brachioradialis is the most superficial muscle along the radial side of the forearm, and forms the lateral border of the cubital fossa (Fig. 49.14). It arises from the proximal two-thirds of the lateral supracondylar ridge of the humerus and the anterior surface of the lateral intermuscular septum. The muscle fibres end above mid-forearm level in a flat tendon which inserts on the lateral side of the distal end of the radius, usually just proximal to its styloid process. Occasionally this attachment may be much more proximal.
The muscle is often fused proximally with brachialis. Its tendon may divide into two or three separately attached slips. In rare instances it is double or absent.

**Relations**

The radial nerve and the anastomosis between the profunda brachii artery.
and the radial recurrent artery lie between the lateral intermuscular septum and brachialis. The tendon is crossed near its distal termination by the tendons of abductor pollicis longus and extensor pollicis brevis. The radial artery is on its ulnar (medial) side.

**Vascular supply**

Brachioradialis is supplied by branches of the radial recurrent artery which pierce the posteromedial surface of the muscle. It also receives branches from the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

**Innervation**

Brachioradialis is innervated by the radial nerve, C5 and 6.

**Action**

Brachioradialis is a flexor of the elbow (despite being supplied by an ‘extensor’ nerve). It acts most effectively with the forearm in mid-pronation. It is minimally active in slow, easy flexions, or with the forearm supine, but generates a powerful burst of activity in both flexion and extension when movement is rapid. Under these conditions it develops a pronounced transarticular component of its force which helps to stabilize the elbow joint by balancing the centrifugal force of rapid swings in either direction.

**Clinical anatomy: testing**

Brachioradialis can be seen and felt when the semi-pronated forearm is flexed against resistance.

**Extensor carpi radialis longus**

**Attachments**

Extensor carpi radialis longus arises mainly from the distal third of the lateral supracondylar ridge of the humerus and the front of the lateral intermuscular septum. Some fibres come from the common tendon of origin of the forearm extensors. The belly ends at the junction of the proximal and middle thirds of the forearm in a flat tendon which runs along the lateral surface of the radius, deep to abductor pollicis longus and extensor pollicis brevis. The tendon then passes under the extensor retinaculum, where it lies in a groove on the back of the radius just behind the styloid process. It inserts on the radial side of the dorsal surface of the base of the second metacarpal, and may send slips to the first or third metacarpal bones. It contributes to the intermetacarpal ligaments.

**Relations**
Extensor carpi radialis longus is partly overlapped by brachioradialis (Fig. 49.14).

**Vascular supply**

Extensor carpi radialis longus receives its principal arterial supply from a single branch from the radial recurrent artery. Additional blood supply comes from branches from the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

**Innervation**

Extensor carpi radialis longus is innervated by the radial nerve, C6 and 7.

**Action**

Extensor carpi radialis longus acts as an extensor and abductor of the wrist and midcarpal joints. It acts in synergism with the finger flexors when making a fist.

**Clinical anatomy: testing**

The muscle belly and tendon of extensor carpi radialis longus can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

**Extensor carpi radialis brevis**

**Attachments**

Extensor carpi radialis brevis arises from the lateral epicondyle of the humerus by a tendon of origin which it shares with other forearm extensors, the radial collateral ligament of the elbow joint, a strong aponeurosis which covers its surface, and adjacent intermuscular septa. Its belly ends at about mid-forearm in a flat tendon which closely accompanies that of the longer carpal extensor to the wrist. The tendon passes under the extensor retinaculum and is attached to the dorsal surface of the base of the third metacarpal on its radial side, distal to its styloid process, and on adjoining parts of the second metacarpal base.

The tendons of both extensor carpi radialis longus and brevis may split into slips, which are variably attached to the second and third metacarpal bones. The muscles themselves may be united or may exchange muscular slips.

**Relations**

Extensor carpi radialis brevis is shorter than extensor carpi radialis longus and is covered by it (Fig. 49.14). The tendon passes deep to abductor pollicis
longus and extensor pollicis brevis, then under the extensor retinaculum, where it lies in a shallow groove on the back of the radius, medial to the tendon of extensor carpi radialis longus, and separated from it by a low ridge. These two tendons share a common synovial sheath.

Vascular supply

Extensor carpi radialis brevis receives its arterial supply principally from two pedicles. One is a single branch from the radial recurrent artery, and the other is a branch of the radial artery which arises about one third of the way down the forearm. There is an additional blood supply proximally from branches from the radial collateral branch of the profunda brachii.

Innervation

Extensor carpi radialis brevis is innervated by the posterior interosseous nerve, C7 and 8.

Action

Extensor carpi radialis brevis acts with extensor carpi radialis longus as an extensor and abductor of the wrist and midcarpal joints. It acts in synergism with the finger flexors when making a fist.

Clinical anatomy: testing

The muscle belly and tendon of extensor carpi radialis brevis can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

Extensor digitorum

Attachments

Extensor digitorum arises from the lateral epicondyle of the humerus via the common extensor tendon, the adjacent intermuscular septa and the antebrachial fascia (Fig. 49.14). It divides distally into four tendons, which pass, in a common synovial sheath with the tendon of extensor indicis, through a tunnel under the extensor retinaculum. The tendons diverge on the dorsum of the hand, one to each finger. The tendon to the index finger is accompanied by extensor indicis, which lies ulnar (medial) to it. On the dorsum of the hand, adjacent tendons are linked by three variable intertendinous connections (juncturae tendinae), which are inclined distally and radially. The digital attachments enter a fibrous expansion on the dorsum of the proximal phalanges to which lumbrical, interosseous and digital extensor tendons all contribute.

The tendons of extensor digitorum may be variably deficient. More
commonly, they are doubled or even tripled in one or more digits, most often the index finger or the middle finger. Occasionally a slip of tendon passes to the thumb. The arrangement of the intertendinous connections on the dorsum of the hand is highly variable. The medial connection is strong and pulls the tendon of the little finger towards that of the ring finger, whereas the connection between the middle two tendons is weak and may be absent.

Relations

The extensor tendon to the index finger lies radial (lateral) to the tendon of extensor indicis. The extensor tendon to the little finger lies radial (lateral) to the tendon of extensor digiti minimi.

Vascular supply

The proximal third of extensor digitorum is supplied by branches from the radial recurrent artery, and the distal two-thirds are supplied by branches from the posterior interosseous artery. The very distal portion is supplied by a perforating branch from the anterior interosseous artery which passes through the interosseous membrane.

Innervation

Extensor digitorum is innervated by the posterior interosseous nerve, C7 and 8.

Action

Extensor digitorum can extend any or all of the joints over which it passes, i.e. wrist, metacarpophalangeal, proximal and distal interphalangeal joints (the latter two via the extensor expansion of the digits). When acting on the metacarpophalangeal joints, extensor digitorum tends to spread the digits apart, an action that is due principally to the different axes of the individual joints imposed by the transverse arch of the hand. This is a 'trick' movement used by patients with interosseous muscle paralysis. The function of the intertendinous bands is not clear, but they may affect the independent extension of digits. Alternatively a junctura can maintain some active extension even when a tendon has been divided in the metacarpal section of the hand, although the extent to which this occurs will depend on the junctura's orientation. For example, some extension of the ring finger may be possible in the absence of its own tendon via the junctura of the middle finger, but the converse does not occur.

Testing

The tendons of extensor digitorum can be readily felt, and usually seen, when the fingers are extended against resistance and the forearm is
pronated.

**Extensor digiti minimi**

**Attachments**

Extensor digiti minimi is a slender muscle medial to, and usually connected with, extensor digitorum (Fig. 49.14). It arises from the common extensor tendon by a thin tendinous slip and adjacent intermuscular septa. It frequently has an additional origin from the antebrachial fascia. Its long tendon slides in a separate compartment of the extensor retinaculum just behind the inferior radio-ulnar joint. Distal to the retinaculum, the tendon typically splits into two, and the lateral slip is joined by a tendon from extensor digitorum. All three tendons are attached to the dorsal digital expansion of the fifth digit, and there may be a slip to the fourth digit.

Extensor digiti minimi is rarely absent, but sometimes it is fused with extensor digitorum.

**Relations**

The tendon of extensor digiti minimi lies ulnar (medial) to the common extensor tendon to the little finger.

**Vascular supply**

Extensor digiti minimi is supplied by branches from the radial recurrent and posterior interosseous arteries, and by terminal branches from the anterior interosseous artery after it has pierced the interosseous membrane.

**Innervation**

Extensor digiti minimi is innervated by the posterior interosseous nerve, C7 and 8.

**Action**

Extensor digiti minimi can extend any of the joints of the little finger, or contribute to wrist extension. It permits extension of the little finger independently of the other digits even in extremes of ulnar or radial wrist deviation.

**Clinical anatomy: testing**

Extensor digiti minimi is tested by extending the little finger while holding the remaining fingers flexed at the metacarpophalangeal joints. This eliminates any simultaneous contraction of extensor digitorum.
**Extensor carpi ulnaris**

**Attachments**

Extensor carpi ulnaris arises from the lateral epicondyle via the common extensor tendon, the posterior border of the ulna (by an aponeurosis shared with flexor carpi ulnaris and flexor digitorum profundus), and overlying fascia (Fig. 49.14). It ends in a tendon that slides in a groove between the head and the styloid process of the ulna, in a separate compartment of the extensor retinaculum, and is ultimately attached to a tubercle on the medial side of the fifth metacarpal base.

**Vascular supply**

Proximally extensor carpi ulnaris receives branches from the radial recurrent artery. Distally, it is supplied by several branches from the posterior interosseous artery.

**Innervation**

Extensor carpi ulnaris is innervated by the posterior interosseous nerve, C7 and 8.

**Action**

Together with extensors carpi radialis longus and brevis, extensor carpi ulnaris acts synergistically with the digital flexors to extend and to fix the wrist when objects are being gripped or when the fist is clenched. Observation shows that it is impossible to grip strongly unless the wrist is extended. Acting with flexor carpi ulnaris, extensor carpi ulnaris adducts the hand.

**Clinical anatomy: testing**

If the wrist is extended and adducted against resistance, and the forearm is pronated and the fingers are extended, extensor carpi ulnaris can be felt lateral to the groove that overlies the posterior subcutaneous border of the ulna.

**Anconeus**

**Attachments**

Anconeus is a small, triangular muscle posterior to the elbow joint and is partially blended with triceps (Fig. 49.14). Anconeus arises by a separate tendon from the posterior surface of the lateral epicondyle of the humerus. Its fibres diverge medially towards the ulna, covering the posterior aspect of the annular ligament, and are attached to the lateral aspect of the olecranon and proximal quarter of the posterior surface of the shaft of the ulna.
The extent to which anconeus fuses with triceps or extensor carpi ulnaris is variable.

**Vascular supply**

Anconeus is supplied by branches from the posterior interosseous recurrent artery. A small number of musculocutaneous perforators reach the skin overlying the muscle.

**Innervation**

Anconeus is innervated by the radial nerve, C6, 7 and 8.

**Action**

Anconeus assists triceps in extending the elbow joint. Its major function is not clear, but it may be the control of ulnar abduction in pronation, which is necessary if the forearm is to turn over the hand without translating it medially. In this way a tool can be revolved 'on the spot' or it can be swept through an arc.

**Deep extensor compartment**

The five deep forearm extensor muscles are abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis (which all act on the thumb), extensor indicis and supinator (Fig. 49.15). Apart from supinator, all are attached proximally only to the forearm bones.
Fig. 49.15 The deep extensor muscles of the left forearm. Note the posterior interosseous artery divides into two main branches shortly after emerging from beneath supinator. One branch follows the posterior interosseous nerve, while the other travels more laterally and gives off fasciocutaneous perforator vessels which supply the posterior interosseous artery flap.

**Abductor pollicis longus**

**Attachments**

Abductor pollicis longus arises from the posterior surface of the shaft of the ulna distal to anconeus, the adjoining interosseous membrane, and the
middle third of the posterior surface of the radius distal to the attachment of supinator (Fig. 49.15). It descends laterally, becoming superficial in the distal forearm, where it is visible as an oblique elevation (Fig. 49.14). The muscle fibres end in a tendon just proximal to the wrist. The tendon runs in a groove on the lateral side of the distal end of the radius accompanied by the tendon of extensor pollicis brevis. It usually splits into two slips, one of which is attached to the radial side of the first metacarpal base, and the other is attached to the trapezium. Slips from the tendon may continue into opponens pollicis or abductor pollicis brevis. Occasionally the muscle itself may be wholly or partially divided.

**Vascular supply**

Abductor pollicis longus is supplied proximally by a lateral branch from the posterior interosseous artery. Distally it is supplied on the medial side by a perforating branch from the anterior interosseous artery.

**Innervation**

Abductor pollicis longus is innervated by the posterior interosseous nerve, C7 and 8.

**Action**

Abductor pollicis longus abducts the wrist joint. Acting with abductor pollicis brevis it aids abduction of the thumb radially (i.e. in the plane of the palm). Acting with the pollicial extensors it extends the thumb at its carpometacarpal joint. The tendon may also stabilize the trapezium upon which the first metacarpal can move.

**Clinical anatomy: testing**

The tendon of abductor pollicis longus can be seen and felt at the radial aspect of the anatomical snuff box when the thumb and wrist are abducted against resistance at the carpometacarpal joint.

**Extensor pollicis longus**

**Attachments**

Extensor pollicis longus is larger than extensor pollicis brevis, whose proximal attachment it partly covers (Fig. 49.14, Fig. 49.15). It arises from the lateral part of the middle third of the posterior surface of the shaft of the ulna below abductor pollicis longus, and the adjacent interosseous membrane. The tendon passes through a separate compartment of the extensor retinaculum in a narrow, oblique groove on the back of the distal end of the radius. It turns around a bony fulcrum, Lister's tubercle, which changes its line of pull from that of the forearm to that of the thumb, and is attached to the
base of the distal phalanx of the thumb. The sides of the tendon are joined on the dorsum of the proximal phalanx by expansions from the tendon of abductor pollicis brevis laterally, and from the first palmar interosseous and adductor pollicis medially.

Relations

After passing around Lister's tubercle, the tendon of extensor pollicis longus crosses the tendons of extensor carpi radialis brevis and longus obliquely (Fig. 49.14). When the thumb is fully extended the tendon is separated from extensor pollicis brevis by a triangular depression or fossa, the so-called 'anatomical snuff-box'. Bony structures can be felt in the floor of this fossa by deep palpation. In proximal to distal order they are the radial styloid, the smooth convex articular surface of the scaphoid, the trapezium, and the base of the first metacarpal. The latter are more easily felt during metacarpal movement, while the scaphoid is more easily felt during adduction and abduction of the hand.

Vascular supply

Extensor pollicis longus is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation

Extensor pollicis longus is innervated by the posterior interosseous nerve, C7 and 8.

Action

Extensor pollicis longus extends the distal phalanx of the thumb. Acting in association with extensor pollicis brevis and abductor pollicis longus, it extends the proximal phalanx and the metacarpal. In continued action, as a consequence of the obliquity of its tendon, extensor pollicis longus adducts the extended thumb and rotates it laterally.

Clinical anatomy: testing

The tendon of extensor pollicis longus can be palpated at the ulnar border of the anatomical snuff-box when the thumb is extended at the interphalangeal joint against resistance. When the thumb is opposed and adducted, abductor pollicis brevis can extend the interphalangeal joint of the thumb, mimicking the action of extensor pollicis longus.

Extensor pollicis brevis

Attachments
Extensor pollicis brevis arises from the posterior surface of the radius distal to abductor pollicis longus, and from the adjacent interosseous membrane (Fig. 49.14, Fig. 49.15). The tendon is inserted into the base of the proximal phalanx of the thumb, and commonly has an additional attachment to the base of the distal phalanx, usually through a fasciculus which joins the tendon of extensor pollicis longus. Extensor pollicis brevis may be absent or fused completely with abductor pollicis longus.

Relations

Extensor pollicis brevis is ulnar (medial) to, and closely connected with, abductor pollicis longus (Fig. 49.14, Fig. 49.15). In the distal forearm, the two muscles emerge between extensor carpi radialis brevis and extensor digitorum, and pass obliquely across the tendons of the radial extensors of the wrist. They cover the distal part of brachioradialis, and pass through the most lateral compartment of the extensor retinaculum in a single synovial sheath, sharing a groove in the distal radius. Ultimately they cross, superficial to the radial styloid process and radial artery, to reach the dorsolateral base of the proximal phalanx of the thumb.

Vascular supply

Extensor pollicis brevis is supplied from branches from the posterior interosseous artery together with perforating branches from the anterior interosseous artery.

Innervation

Extensor pollicis brevis is innervated by the posterior interosseous nerve, C7 and 8.

Action

Extensor pollicis brevis extends the proximal phalanx and metacarpal of the thumb.

Clinical anatomy: testing

The tendon of extensor pollicis brevis can be felt at the radial border of the anatomical snuff-box, lying medial to the tendon of abductor pollicis longus, when the metacarpophalangeal joint of the thumb is extended against resistance.

Extensor indicis

Attachments

Extensor indicis is a narrow, elongated muscle which lies medial and parallel
to extensor pollicis longus (Fig. 49.15). It arises from the posterior surface of the ulna distal to extensor pollicis longus, and the adjacent interosseous membrane. Its tendon passes under the extensor retinaculum in a common compartment with the tendons of extensor digitorum. Opposite the head of the second metacarpal it joins the ulnar side of the tendon of extensor digitorum which serves the index finger.

Extensor indicis occasionally sends accessory slips to the extensor tendons of other digits. Rarely its tendon may be interrupted on the dorsum of the hand by an additional muscle belly (extensor indicis brevis manus).

Relations

The tendon of extensor indicis lies on the ulnar aspect of the extensor digitorum tendon to the index finger on the dorsum of the hand.

Vascular supply

Extensor indicis is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation

Extensor indicis is innervated by the posterior interosseous nerve, C7 and 8.

Action

Extensor indicis helps to extend the index finger and the wrist. It permits extension of the index finger independently of the other digits, even in extremes of ulnar or radial wrist deviation.

Clinical anatomy: testing

Extensor indicis is tested by extending the index finger while holding the remaining fingers flexed at the metacarpophalangeal joints. This eliminates the effects of any simultaneous contraction of extensor digitorum.

Supinator

Attachments

Supinator surrounds the proximal third of the radius and has superficial and deep layers (Fig. 49.15). The two parts arise together, the superficial by tendinous, and the deep by muscular fibres, from the lateral epicondyle of the humerus; the radial collateral ligament of the elbow joint and the anular ligament of the superior radio-ulnar joint; the supinator crest of the ulna and the posterior part of the triangular depression in front of it; and an
aponeurosis which covers the muscle. Supinator is attached distally to the lateral surface of the proximal third of the radius, down to the insertion of pronator teres. The radial attachment extends on to the anterior and posterior surfaces between the anterior oblique line and the fainter posterior oblique ‘ridge’ (Fig. 49.4).

Supinator is subject to frequent variation, and small parts of the muscle have acquired individual names, e.g. lateral and medial tensors of the annular ligament.

**Relations**

The posterior interosseous nerve enters the forearm by passing between the superficial and deep heads of supinator.

**Vascular supply**

The superficial part of supinator is supplied by branches from the radial recurrent artery. The deep part of supinator is supplied by branches from the posterior interosseous artery and the posterior interosseous recurrent artery.

**Innervation**

Supinator is innervated by the posterior interosseous nerve, C6 and 7 as it traverses the muscle.

**Action**

Supinator rotates the radius so as to bring the palm to face anteriorly. It acts alone in slow, unopposed supination, and together with biceps brachii in fast or forceful supination. An object which may potentially be heavy is often picked up with the forearm initially pronated. The more powerful supinators lift the object against gravity, and rotation is often combined with increasing elbow flexion to bring the object towards the eyes.

**Clinical anatomy: testing**

Supinator is too deep to be palpated and independent testing is difficult. Biceps is inactive on supination with the elbow fully extended, therefore this must be produced by supination alone and can be used to test its function.
ARteries

Radial Artery

The radial artery is smaller than the ulnar artery, yet appears a more direct continuation of the brachial artery (Fig. 49.12, Fig. 49.13, see Fig. 49.19). It normally starts 1 cm distal to the flexion crease of the elbow. It descends along the lateral side of the forearm, accompanied by paired venae comitantes, from the medial side of the neck of the radius to the wrist, where it is palpable between flexor carpi radialis medially and the salient anterior border of the radius. The artery is medial to the radial shaft proximally, and anterior to it distally. Proximally it is overlapped anteriorly by the belly of brachioradialis, but elsewhere in its course it is covered only by the skin, and superficial and deep fasciae. Its posterior relations in the forearm are successively the tendon of biceps, supinator, the distal attachment of pronator teres, the radial head of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus and the lower end of the radius (where its pulsation is most accessible). Brachioradialis is lateral to the artery throughout its length. Pronator teres is medial to the proximal part of the artery and the tendon of flexor carpi radialis is medial to the distal portion. The superficial radial nerve lies lateral to the middle third of the radial artery: multiple branches from the artery supply the nerve throughout its length.

The radial artery may occasionally arise from the continuation of a superficial brachial artery, or as a high proximal division of an otherwise normal brachial artery. It can give rise to the common interosseous artery.

The course and distribution of the radial artery in the wrist and hand are described on page 890.

Branches in the forearm

Radial Recurrent Artery

The radial recurrent artery is discussed on page 835.

Cutaneous branches

Cutaneous branches emerge between brachioradialis and pronator teres in the proximal third of the forearm. The largest perforator, which is also the largest in the forearm, has been named the inferior cubital artery. It reaches the deep fascia by passing superficially between brachioradialis and pronator teres in the apex of the antecubital fossa. It lies lateral to the tendon of biceps, emerging between the median cubital vein and its communicating branch to the venae comitantes of the radial artery. In the distal two-thirds of the forearm, the cutaneous perforators emerge through the fascia between brachioradialis and flexor carpi radialis and between flexor carpi radialis and flexor digitorum
superficialis and fan out at the level of the deep fascia. These vessels anastomose with their counterparts from the ulnar artery and the posterior interosseous artery.

The fasciocutaneous branches provide the anatomical basis for raising a skin flap containing the whole width of forearm skin, either pedicled or as a free flap, based on the radial artery and its venae comitantes. Known as the radial forearm fasciocutaneous flap, it is used for reconstructing areas of missing tissue elsewhere in the body. It is possible to incorporate the lateral aspect of the radius with the flap because a few fascioperiosteal branches supply this part of the bone.

Muscular branches

Muscular branches are distributed to the muscles on the radial side of the forearm.

Ulnar artery

The ulnar artery is the larger terminal branch of the brachial artery (Fig. 49.12, Fig. 49.13, see Fig. 49.19). It starts 1 cm distal to the flexion crease of the elbow and reaches the medial side of the forearm midway between elbow and wrist. In the forearm the artery initially lies on brachialis and deep to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. It subsequently lies on flexor digitorum profundus, between flexor carpi ulnaris and flexor digitorum superficialis, and is covered by the skin, superficial and deep fasciae. The median nerve is a medial relation for approximately 2.5 cm distal to the elbow, and then crosses the artery, from which it is separated by the ulnar head of pronator teres. The ulnar nerve lies medial to the distal two-thirds of the artery, which supplies the nerve throughout its length. The palmar cutaneous branch of the ulnar nerve descends along the ulnar artery to reach the hand. The ulnar artery crosses the flexor retinaculum lateral to the ulnar nerve and pisiform bone to enter the hand.

The ulnar artery is accompanied throughout its length by venae comitantes.

The ulnar artery may arise proximal to the elbow, usually from the brachial artery, when it usually lies superficial to the forearm flexors under the deep fascia: only rarely is it subcutaneous. When this occurs, the brachial artery supplies the common interosseous and the ulnar recurrent arteries.

The course and distribution of the ulnar artery in the wrist and hand are described on page 893.

Branches in the forearm

Anterior and posterior ulnar recurrent arteries

The anterior and posterior ulnar recurrent arteries are described on page 835.
Common interosseous artery

The common interosseous artery is a short branch of the ulnar artery (Fig. 49.13, see Fig. 49.19). It arises just distal to the radial tuberosity and passes back to the proximal border of the interosseous membrane, where it divides into the anterior and posterior interosseous arteries. Occasionally, the common interosseous artery is a branch of the radial artery.

Anterior interosseous artery

The anterior interosseous artery descends on the anterior aspect of the interosseous membrane with the anterior interosseous branch of the median nerve (see Fig. 49.19). It is overlapped by contiguous sides of flexor digitorum profundus and flexor pollicis longus. Shortly after its origin, it usually gives off a slender median artery. This accompanies and supplies the median nerve as far as the palm, where it may join the superficial palmar arch or end as one or two palmar digital arteries. (The median artery can also arise from the ulnar or the common interosseous artery.)

Muscular and nutrient branches from the anterior interosseous artery pierce the interosseous membrane to supply deep extensor muscles and the radius and ulna respectively. A branch descends deep to pronator quadratus before piercing the interosseous membrane to join the anterior ‘carpal' arch.

The anterior interosseous artery proper leaves the anterior compartment by piercing the interosseous membrane proximal to pronator quadratus. It anastomoses with the posterior interosseous artery in the posterior compartment of the forearm, and travels through a tunnel under the extensor retinaculum with the tendons of the digital extensors before joining the dorsal carpal arch. Three small cutaneous perforating branches supply the skin over the lower lateral border of the forearm.

Posterior interosseous artery

The posterior interosseous artery is usually smaller than the anterior (Fig. 49.15, Fig. 49.17, Fig. 49.18). It passes dorsally between the oblique cord and proximal border of the interosseous membrane and then between supinator and abductor pollicis longus. It descends deep in the groove between extensor carpi ulnaris and the extensor digiti minimi part of extensor digitorum. While in the groove it gives rise to multiple muscular branches which supply these muscles and fasciocutaneous perforators which travel in the intermuscular septum between extensor carpi ulnaris and extensor digiti minimi. These fasciocutaneous vessels provide the anatomical basis for raising a dorsal forearm skin flap, which is usually pedicled, based on the posterior interosseous artery and its venae comitantes. Known as the posterior interosseous artery flap, it is used for reconstructing areas of missing tissue in the forearm and proximal part of the hand.
The posterior interosseous artery accompanies the deep branch of the radial nerve (posterior interosseous nerve) on abductor pollicis longus. Distally it anastomoses with the terminal part of the anterior interosseous artery and the dorsal carpal arch.

Sometimes the posterior interosseous artery disappears halfway down the forearm, in which case the anterior interosseous artery pierces the interosseous membrane more proximally to anastomose with it. Rarely no anastomosis
occurs between the anterior and the posterior interosseous arteries.

Posterior interosseous recurrent artery

The posterior interosseous recurrent artery leaves the posterior interosseous artery near its origin and ascends between the lateral epicondyle and olecranon, either on or through supinator, and deep to anconeus. It anastomoses with the middle collateral branch of the profunda brachii artery, posterior ulnar recurrent and ulnar collateral arteries. Occasionally the artery is absent.

Cutaneous branches

The cutaneous perforators of the ulnar artery reach the skin by passing along the fascial septum between flexor carpi ulnaris and flexor digitorum superficialis throughout the length of the forearm. A constant dorso-ulnar perforator vessel is given off distally 2–5 cm proximal to the pisiform and it accompanies the dorsal cutaneous branch of the ulnar nerve. The vessel emerges between flexor carpi ulnaris and extensor carpi ulnaris. A few small musculocutaneous perforators reach the skin via flexor carpi ulnaris and anastomose with their counterparts derived from the radial and the posterior interosseous arteries.

Muscular branches

Muscular branches arise directly from the main vessel and are distributed to the muscles on the ulnar side of the forearm.
VEINS

Deep veins

The venae comitantes running with the radial and ulnar arteries drain the deep and superficial palmar venous arches respectively. They unite near the elbow as paired brachial veins. The radial veins are smaller, and receive the deep dorsal veins of the hand. The ulnar veins drain the deep palmar venous arch, and connect with superficial veins near the wrist. Near the elbow they receive the venae comitantes of the anterior and posterior interosseous arteries, and a large branch connects them to the median cubital vein.

Superficial veins

Cephalic vein

The cephalic vein (see Fig. 45.5) usually forms over the ‘anatomical snuff-box’ from the radial end of the dorsal venous plexus. It curves proximally around the radial side of the forearm to gain its ventral aspect, and receives veins from both aspects of the forearm. Distal to the elbow a branch, the median cubital vein, diverges proximomedially to reach the basilic vein. The median cubital vein is joined by a branch from the deep veins.

The further course of the cephalic vein is described in the arm on page 828.

Accessory cephalic vein

The accessory cephalic vein may arise either in a dorsal forearm plexus or from the ulnar side of the dorsal venous network in the hand. It joins the cephalic vein distal to the elbow. A large oblique vein often connects the basilic and cephalic veins dorsally in the forearm.

Basilic vein

The basilic vein starts medially in the dorsal venous network of the hand (Fig. 45.5). It ascends posteromedially in the forearm, inclining forwards to the anterior surface distal to the elbow, where it is joined by the median cubital vein. It then ascends superficial to and between biceps and pronator teres, and is crossed by filaments of the medial cutaneous nerve of the forearm which pass both superficial and deep to the vein.

The course of the basilic vein in the arm is described on page 828.

Median vein

The median vein (Fig. 45.5) of the forearm drains the superficial palmar venous plexus and ascends through the anterior part of the forearm to join
either the basilic or median cubital vein. It may divide distal to the elbow to join both veins.
INNERVATION

Median nerve

The median nerve usually enters the forearm between the heads of pronator teres (Fig. 49.12, Fig. 49.13, Fig. 49.16, Fig. 49.17, Fig. 49.18). (Occasionally the nerve passes posterior to both heads of pronator teres, or it may pass through the humeral head). It crosses to the lateral side of the ulnar artery, from which it is separated by the deep head of pronator teres. It passes behind a tendinous bridge between the humero-ulnar and radial heads of the flexor digitorum superficialis, and descends through the forearm posterior and adherent to flexor digitorum superficialis and anterior to flexor digitorum profundus. About 5 cm proximal to the flexor retinaculum it emerges from behind the lateral edge of flexor digitorum superficialis, and becomes superficial just proximal to the wrist. Here it lies between the tendons of flexor digitorum superficialis and flexor carpi radialis, projecting laterally from beneath the tendon of palmaris longus (Fig. 49.13, Fig. 49.19). It then passes deep to the flexor retinaculum into the palm. In the forearm the median nerve is accompanied by the median branch of the anterior interosseous artery.

Fig. 49.16 Transverse section through the left forearm at the level of the radial tuberosity: proximal aspect.

The course and distribution of the median nerve in the wrist and hand is described on page 895.
Martin–Gruber connection

Multiple communicating branches between the median nerve (and sometimes the anterior interosseous nerve) arise proximally and pass medially between flexors digitorum superficialis and profundus, deep to the ulnar artery, and join the ulnar nerve. This motor fibre communication (commonly referred to as the Martin–Gruber connection) is estimated to be present in 17% of individuals. It results in a median nerve innervation of a variable number of intrinsic muscles of the hand (Leibovic & Hastings 1992), and presumably explains why isolated ulnar and median nerve lesions can sometimes be unpredictable in terms of the pattern of intrinsic muscle paralysis.

Branches in the forearm

Anterior interosseous nerve

The anterior interosseous nerve branches posteriorly from the median nerve between the two heads of pronator teres, just distal to the origin of its branches to the superficial forearm flexors and proximal to the point at which the median nerve passes under the tendinous arch of flexor digitorum superficialis. With the anterior interosseous artery it descends anterior to the interosseous membrane, between and deep to flexor pollicis longus and flexor digitorum profundus. It supplies flexor pollicis longus and the lateral part of flexor digitorum profundus (which sends tendons to the index and middle finger). Terminally, the anterior interosseous nerve lies posterior to pronator quadratus, which it supplies via its deep surface. It also supplies articular branches to the distal radio-ulnar, radiocarpal and carpal joints.

Anterior interosseous nerve syndrome

The anterior interosseous nerve may be affected with the median nerve or by itself in any of the causes of pronator syndrome (p. 836). Median nerve compression is typically caused by pressure from fascial bands on the deep head of the pronator teres or the tendinous radial attachment of flexor digitorum superficialis. Anterior interosseous nerve palsy may be due to external pressure, a form of ‘Saturday night palsy’, and sometimes by tight grip in association with pronation without obvious cause. It may be a manifestation of neuralgic amyotrophy and tends to resolve spontaneously over several months. A variety of aberrant muscles, e.g. an accessory head of flexor pollicis longus, palmaris profundus, or flexor carpi radialis brevis, have all been described as causing entrapment neuropathy of the anterior interosseous nerve.

An anterior interosseous nerve palsy causes weakness of pinch grip due to involvement of flexor pollicis longus and flexor digitorum profundus to the index finger. Innervation of flexor digitorum profundus to the middle finger is rather variable, and therefore this muscle may or may not be weak. The branches to these three muscles may arise separately from the median nerve, so that isolated weakness of the terminal phalanx to the thumb or index finger may occur. Pronator quadratus is also involved but is not clinically significant. Anterior interosseous nerve palsy can be distinguished from pronator syndrome because there are no sensory symptoms. The treatment is exploration of the nerve and surgical decompression.

Muscular branches
Muscular branches are given off near the elbow to all the superficial flexor muscles except flexor carpi ulnaris, i.e. to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. The branch to the part of flexor digitorum superficialis which serves the index finger is given off near mid-forearm and may be derived from the anterior interosseous nerve.

Other branches

Articular branches, arising at or just distal to the elbow joint, supply the joint and the proximal radio-ulnar joint. The palmar cutaneous branch is described on page 895.

Ulnar nerve

The ulnar nerve descends on the medial side of the forearm, lying on flexor digitorum profundus (Fig. 49.13, Figs 49.16–49.19). Proximally it is covered by flexor carpi ulnaris: its distal half lies lateral to the muscle and is covered only by skin and fasciae. In the upper third of the forearm, the nerve is distant from the ulnar artery, but more distally it comes to lie close to the medial side of the artery. About 5 cm proximal to the wrist it gives off a dorsal branch which continues distally into the hand, anterior to the flexor retinaculum on the lateral side of the pisiform and posteromedial to the ulnar artery. It passes deep to the superficial part of the retinaculum (in Guyon’s canal) with the artery and divides into superficial and deep terminal branches.

The course and distribution of the ulnar nerve in the hand is described on page 897.

Muscular branches

There are usually two muscular branches. They begin near the elbow and supply flexor carpi ulnaris and the medial half of flexor digitorum profundus.

Palmar cutaneous branch

The palmar cutaneous branch arises about mid-forearm. It descends on the ulnar artery, which it supplies, and then perforates the deep fascia to end in the palmar skin, after communicating with the palmar branch of the median nerve. It sometimes supplies palmaris brevis.

Dorsal branch

The dorsal branch of the ulnar nerve is described on page 897.

Radial nerve

There is some variation in the level at which branches of the radial nerve arise from the main trunk in different subjects (Fig. 49.12, Fig. 49.13, Fig. 49.17, Fig. 49.18). Branches to extensor carpi radialis brevis and supinator may arise from the main trunk of the radial nerve or from the proximal part of the posterior interosseous nerve, but almost invariably above the arcade of Frohse.

Radial tunnel syndrome

Radial tunnel syndrome is an entrapment neuropathy of the radial nerve near the elbow, where four structures can potentially cause compression of the nerve. These
are fibrous bands (which can tether the radial nerve to the radiohumeral joint); the sharp tendinous medial border of extensor carpi radialis brevis; a leash of vessels from the radial recurrent artery as it passes to supply brachioradialis and extensor carpi radialis longus; the arcade of Frohse, which is the free aponeurotic proximal edge of the superficial part of supinator (see Fig. 48.6).

Usually the only presenting symptom is pain over the extensor mass just distal to the elbow. There is no sensory disturbance or motor loss, but there is frequently tenderness along the course of the radial nerve over the radial head. The pain is exacerbated when the elbow is extended and the wrist is passively flexed and pronated, or extended and supinated against resistance. Extension of the middle finger against resistance when the elbow is fully extended also may lead to increased pain. These manoeuvres tighten the anatomical structures which cause compression.

Superficial terminal branch

The superficial terminal branch descends from the lateral epicondyle anterolaterally in the proximal two-thirds of the forearm, initially lying on supinator, lateral to the radial artery and behind brachioradialis. In the middle third of the forearm it lies behind brachioradialis, close to the lateral side of the artery, and is successively anterior to pronator teres, the radial head of flexor digitorum superficialis and flexor pollicis longus. It usually leaves the artery 7 cm proximal to the wrist and passes deep to the tendon of brachioradialis. It curves round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves. On the dorsum of the hand it usually communicates with the posterior and lateral cutaneous nerves of the forearm.

As the nerve crosses the lateral aspect of the radius it is superficial and relatively unprotected: it is easily compressed here by tight bracelets, watch straps and handcuffs.

Radial sensory nerve entrapment (Wartenberg’s disease)

Entrapment of the superficial radial nerve can occur as the nerve emerges from beneath the edge of the brachioradialis tendon about 6 cm proximal to the radial styloid; it is probably pinched by the scissoring effect of brachioradialis and extensor carpi radialis brevis tendons. The condition is frequently associated with previous trauma in this region. The symptoms are pain and paraesthesia over the radial aspect of the dorsum of the wrist and hand.

Posterior interosseous nerve

The posterior interosseous nerve is the deep terminal branch of the radial nerve (Fig. 49.15, Fig. 49.16). It reaches the back of the forearm by passing round the lateral aspect of the radius between the two heads of supinator. It supplies extensor carpi radialis brevis and supinator before entering supinator: as it passes through the muscle it supplies it with additional branches. The branch to extensor carpi radialis brevis may arise from the beginning of the superficial branch of the radial nerve. As it emerges from supinator posteriorly, the posterior interosseous nerve gives off three short branches to extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, and two longer branches, a medial to extensor pollicis longus and extensor indicis, and a lateral which supplies abductor pollicis longus and extensor pollicis brevis. The
nerve at first lies between the superficial and deep extensor muscles, but at the distal border of extensor pollicis brevis it passes deep to extensor pollicis longus and, diminished to a fine thread, descends on the interosseous membrane to the dorsum of the carpus. Here it presents a flattened and somewhat expanded termination or 'pseudoganglion', from which filaments supply the carpal ligaments and articulations. Articular branches from the posterior interosseous nerve supply carpal, distal radio-ulnar and some intercarpal and intermetacarpal joints. Digital branches supply the metacarpophalangeal and proximal interphalangeal joints.

The distal portion of the nerve lies in a separate fascial sheath in the radial, deep aspect of the fourth dorsal compartment of the extensor retinaculum of the wrist, where it is located deep to extensor digitorum and extensor indicis. This portion of the nerve can be used as a donor nerve for grafting segmental digital nerve defects, as there is no clinically discernible donor site deficit.

Posterior interosseous nerve palsy

There are many causes of posterior interosseous nerve palsy. These include trauma and inflammatory swellings, as well as entrapment at the same anatomical sites that can cause radial tunnel syndrome. Pain is similar in nature to that of radial tunnel syndrome and is later accompanied by weakness and paralysis. When fully developed, there is inability to extend the fingers at the metacarpophalangeal joints, weakness of thumb extension and abduction. There is weakness and radial deviation of wrist extension because extensor carpi ulnaris is usually affected, while the radial wrist extensors and brachioradialis are normal (because their nerve supply is given off proximal to the origin of the posterior interosseous nerve). There are no sensory disturbances, because the superficial radial nerve arises above this level.

Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm has already divided into anterior and posterior branches before it enters the forearm (see Fig. 45.15). The larger anterior branch usually passes in front of, occasionally behind, the median cubital vein, and descends anteromedially in the forearm to supply the skin as far as the wrist. It curves round to the back of the forearm, descending on its medial border to the wrist, supplying the skin. It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the terminal branch of the radial nerve by branches which pass around its radial border. Its trunk gives rise to a slender recurrent branch which extends along the cephalic vein as far as the middle third of the upper arm, distributing filaments to the skin over the distal third of the anterolateral surface of the upper arm close to the vein. At the wrist joint the lateral cutaneous nerve of the forearm is anterior to the radial artery. Some filaments pierce the deep fascia and accompany the artery to the dorsum of the carpus. The nerve then passes to the base of the thenar eminence, where it ends in
cutaneous rami. It has branches which connect with the terminal branch of the radial nerve and the palmar cutaneous branch of the median nerve.

**Posterior cutaneous nerve of the forearm**

The posterior cutaneous nerve of the forearm passes along the dorsum of the forearm to the wrist. It supplies the skin along its course and near its end joins the dorsal branches of the lateral cutaneous nerve of the forearm (see Fig. 45.15).

CHAPTER 50 – Wrist and hand

SKIN AND SOFT TISSUE

SKIN

Dorsal skin versus palmar skin

The skin over the dorsum of the hand is thin and mobile and this allows for flexion at the metacarpophalangeal and interphalangeal joints. The dorsal skin is frequently hirsute over the dorsal aspect of the proximal phalanges and the ulnar aspect of the dorsum of the hand. In comparison, the palm is adapted for padding and anchorage. The palmar skin and the skin over the volar surface of the digits is thick and hairless, and has a well-defined stratum lucidum, a higher density of nerve endings, and eccrine sweat glands, but no sebaceous glands.

Skin creases and fingerprints

Flexure lines commonly crease the skin across the flexor surfaces of the wrist and hand (Fig. 50.1). Though not all directly over their functionally related subjacent skeletal joints, they are produced by adhesion of the skin to subjacent deep fascia and are sites of folding of the skin during movement. These flexures are useful landmarks. Less regular, but quite prominent, crease-line complexes are centred over the dorsal (extensor) aspects of the radiocarpal, carpal, metacarpophalangeal and interphalangeal joints. They are mainly transverse but display varying curvatures. During flexion the dorsal skin is stretched and the lines become less prominent (but can still be identified). During extension the now redundant skin becomes increasingly puckered and the lines are finally maximally prominent. (For a general review of 'skin lines' see p. 160.)
Near the junction of the carpus and forearm there are usually three anterior transverse lines. The proximal marks the proximal limit of the flexor synovial sheaths, an intermediate line overlies the wrist joint, and a distal line is at the proximal border of the flexor retinaculum.

In the palm a curved radial longitudinal line encircles the thenar eminence,
ending at the radial (lateral) margin of the palm. Several less constant longitudinal lines lie medial and roughly parallel to it. Proximal and distal transverse lines ascend medially across the palm. The proximal line begins at the distal end of the radial longitudinal line and runs obliquely to the middle of the hypothenar eminence across the shafts of the metacarpals. The distal line begins at or near the cleft between the index and middle finger and crosses the palm with a proximal convexity over the second to fourth metacarpal heads, near the proximal ends of the fibrous flexor sheaths.

The second to fifth digits show proximal, middle and distal sets of transverse lines. The proximal, often double, are at the digital roots, approximately 2 cm distal to the metacarpophalangeal joints. The middle lines are typically double, the proximal line lying directly over the proximal interphalangeal joint. The distal lines are usually single, and lie proximal to the distal interphalangeal joints: their levels are sometimes marked by a fainter, more distal line. The free pollicial base is partly encircled by a line which starts on the radial side and crosses distally over the metacarpophalangeal joint to end between the thumb and index finger level with the base of the proximal pollicial phalanx. There is a second, shorter crease usually 1 cm distal to this line. There are two lines comparable to the middle digital lines in other digits opposite the interphalangeal joint of the thumb (see also p. 160).

Cutaneous vascular supply

The skin of the volar aspect of the wrist is supplied directly by cutaneous branches from the superficial palmar branch of the radial artery, the ulnar artery and occasionally the median artery if it is large enough (Fig. 50.2). The skin over the thenar eminence is supplied by small perforating branches from the superficial palmar branch of the radial artery and the princeps pollicis. The skin over the hypothenar eminence is supplied by perforating branches from the ulnar artery, some of which pass through palmaris brevis. The remainder of the palm is supplied by small perforating branches from the common palmar digital arteries which pierce the palmar aponeurosis, and small branches from the radialis indicis artery. The blood supply to the volar aspect of the digital skin comes from small branches from each digital artery. At the level of the distal phalanx the two digital arteries typically form an H-shaped anastomosis from which cutaneous perforators fan out within the pulp. Deep digital veins accompanying the digital arteries are usually very small and frequently absent. More commonly, superficial palmar veins tend to pass dorsally and drain into the larger superficial dorsal venous system.
The skin of the dorsal aspect of the wrist is supplied by branches from a plexus overlying the extensor retinaculum. Branches from the radial artery, including its dorsal carpal branch, dorsal carpal branch of the ulnar artery, and anterior and posterior interosseous arteries all contribute to this plexus. The blood supply to the dorsum of the hand arises from longitudinal rows of four or five tiny branches from each of the dorsal metacarpal arteries, which usually arise either from the radial artery directly or the dorsal carpal arch. At
the level of the neck of the metacarpals, where the second, third and fourth dorsal metacarpal arteries communicate with branches from the corresponding common palmar digital arteries, a large cutaneous perforating branch passes proximally to supply an area of skin as far as the dorsal aspect of the wrist.

The blood supply to the dorsum of the fingers comes proximally from the terminal branches of the dorsal metacarpal arteries – supplying a region as far distally as the proximal interphalangeal joint – as well as from dorsal branches of the palmar digital arteries which are given off at each phalangeal level. At the level of the distal phalanx the cutaneous supply comes from three dorsal arcades: a superficial arcade over the base of the distal phalanx, and two distal subungual arcades. The skin of the dorsum of the thumb is supplied by longitudinal axial branches of the princeps pollicis and dorsal branches from the palmar digital arteries.

Cutaneous innervation

The skin of the volar aspect of the wrist is innervated by the terminal branches of the lateral and medial cutaneous nerves of the forearm. The skin of the palm is innervated by the palmar branches of the ulnar nerve and the palmar branch of the median nerve (Fig. 50.3; see also Fig. 50.45. The skin of the volar aspect of the thumb, index, middle and radial aspect of the ring fingers is supplied by cutaneous branches of the median nerve, while that of the little finger and ulnar side of the ring finger is supplied by the ulnar nerve.
Fig. 50.3 Cutaneous nerve supply to the hand. A, Volar aspect. B, Dorsal aspect.
The cutaneous innervation of the radial aspect of the dorsum of the wrist and hand, as well as the dorsal aspect of the radial three and a half digits as far distally as the nail bed, arises from the terminal branches of the radial nerve, the dorsal digital nerves. Between two and five dorsal digital nerves supply each digit. The cutaneous innervation of the ulnar aspect of the dorsum of the wrist and hand, and the dorsal aspect of the ulnar one and a half digits as
far distally as the nail bed, arises from the dorsal branch of the ulnar nerve, again ending as dorsal digital nerves. The skin of the dorsum of the middle and distal phalanges is also supplied by dorsal branches of the palmar digital nerves.
NAIL APPARATUS

The nail apparatus consists of the nail plate, proximal and lateral nail folds, nail matrix, nail bed and hyponychium. It is described on page 154.
SOFT TISSUE

Palmar fascial complex

The palmar fascia is a three-dimensional ligamentous system composed of longitudinal, transverse and vertical fibres (Fig. 50.4).

Fig. 50.4 Palmar aponeurosis and distal fascial complex. A, Schematic diagram of the palmar fascia. B, More detailed view of structures at the web space. C, Fate of the distal longitudinal fibres. D, E, Normal digital fascia.

Longitudinal fibre system

The longitudinal fibres represent the phylogenetically degenerated metacarpophalangeal joint flexor. They run distally from the palmaris longus tendon or the flexor retinaculum of the wrist across the whole width of the central third of the palm, producing four well-defined longitudinal bundles to the index, middle, ring and little fingers. A less well-defined bundle passes to the thumb. Distal to the transverse fibres of the palmar aponeurosis the longitudinal fibres pass in three layers (McGrouther 1982). The most superficial longitudinal fibres (layer 1) are inserted superficially into the skin of the distal palm between the distal palmar crease and the
proximal digital crease. Some superficial fibres pass distally into the palmar midline of the digit. Deeper longitudinal fibres (layer 2) pass deep to the natatory ligament and neurovascular bundles into the apex of the web space skin and into the fingers themselves where they are continuous with Cleland's ligaments and the lateral digital sheet. These are known as the spiral bands of Gosset. Deeper still, the longitudinal fibres in layer 3 perforate the deep transverse metacarpal ligament to pass around the sides of the metacarpophalangeal joint and attach to the metacarpal bone and proximal phalanx, and extensor tendon.

Transverse fibre system

The transverse fibre system consists of the natatory ligament (also known as superficial transverse metacarpal ligament), the transverse fibres of the palmar aponeurosis (also known as fibres of Skoog), and the transverse metacarpal ligament (also known as the deep transverse metacarpal ligament).

*Natatory ligament (superficial transverse metacarpal ligament)*

The fibres of the natatory ligament (superficial transverse metacarpal ligament) cross the apex of the web skin and extend into the digit to blend with the lateral digital sheet, thus limiting the spreading of the skin of the distal palm and the separation of the adjacent fingers. The natatory ligament in the first web is called the distal commissural ligament.

*Transverse fibres of the palmar aponeurosis*

The transverse fibres of the palmar aponeurosis (fibres of Skoog) lie more proximally than the natatory fibres and represent the deepest layer of the palmar fascia. They lie proximal to the distal palmar crease in a band approximately 2 cm wide, and connect the anterior fibres of the flexor tendon sheaths with one another and to the fasciae over the thenar and hypothenar muscles groups. The extension to the first ray is called the proximal commissural ligament.

*Transverse metacarpal ligament*

The strong transverse fibres of the transverse metacarpal ligament are deep to the palmar aponeurosis and flexor sheaths. They connect the metacarpal heads of the index to little fingers by their attachment with the volar plates.

Vertical fibre system

The vertical fibres are more delicate, and pass from the dermis, between the longitudinal and transverse fibres, to the fibrous flexor sheaths and the metacarpal bones. They are concentrated on either side of the palmar skin creases as well as the thenar and hypothenar eminences.

A series of vertical septa lie deep to the transverse fibres of the palmar aponeurosis, and connect it to the underlying deep transverse ligament. They provide compartments which contain the flexor tendons and the lumbricals and neurovascular bundles.

*Dupuytren's disease*
Dupuytren's disease (contracture) is a progressive condition of uncertain aetiology resulting from fibrous contracture of the palmar aponeurosis: the little and ring fingers are especially affected. Longitudinal thickening in the palm produces cords and thickened nodules which can progress to flexion deformities of the metacarpophalangeal and proximal interphalangeal joints of the affected fingers. The palmar aponeurosis only extends as far as the sides of the middle phalanx, therefore the distal interphalangeal joint is uncommonly involved. Indeed, in advanced cases, the distal interphalangeal joint can be hyperextended as the distal phalanx is pushed backwards against the palm.

The pattern of fascial involvement in this condition can be complex. For example, the normal anatomical position of the digital nerves and arteries may be distorted because they are often displaced medially. Since surgical treatment involves excising the affected area of palmar fascia, the digital nerves and arteries may be at risk in this procedure.

A similar contracture may affect the plantar fascia in the sole of the foot.

**Digital fascial complex**

The superficial fascia within the finger is fibrofatty in the palmar and dorsal aspects, but more sheet-like laterally, where it is termed the lateral digital sheet. Within the core of the finger the fascia is thickened in areas, forming the flexor sheath, Cleland's, Grayson's and Landsmeer's ligaments (Fig. 50.4). The flexor sheath is discussed in detail on page 879. Cleland's ligaments extend from the sides of the phalanges, pass dorsal to the neurovascular bundles and insert into the lateral digital sheet. Grayson's ligaments are more delicate, may even be discontinuous and pass from the lateral sides of the phalanges volar to the neurovascular bundles to insert into the lateral digital sheet. Landsmeer's ligaments are inconsistent anatomical structures made up of transverse and oblique retinacular ligaments (see Fig. 50.30). The transverse retinacular ligament passes from the A3 pulley of the fibrous flexor sheath at the level of the proximal interphalangeal joint to the lateral border of the lateral extensor band. The oblique retinacular ligament lies deep to the transverse retinacular ligament. It originates from the lateral aspect of the proximal phalanx and flexor sheath (A2 pulley) and passes volar to the axis of rotation of the proximal interphalangeal joint in a dorsal and distal direction to insert into the terminal extensor tendon.
Functions of the fascia of the hand

The fascial continuum of the hand performs a number of different, but inter-related, functions. It channels and provides a gliding surface for structures in transit between the forearm and the digits; transmits loads; anchors the skin; protects underlying vessels; and provides a framework for muscle attachments.

Channelling of structures in transit between forearm and digits

The vertical septa act as spacers between the tendons and neurovascular bundles of the individual digital rays. Where tendons change direction around a concave surface the channels are thickened. They perform a retinacular role, forming sheaths with specialized pulleys to prevent the tendon springing away from the underlying skeleton (see flexor tendon sheaths, p. 879).

Transmission of loads

At points where compressive loading is applied to the hand, such as the finger pulp and palm, loculi of fat act as shock absorbers. The loculi are contained within defined fibrous boundaries, which means that the shape, but not the volume, of each loculus can change. The compliance or deformability of the boundaries determines the amount of shock absorption. Local ‘turgor’ (deformability) and blood volume are measures of this anatomical property.

The palm also contains much larger fibrous compartments between skin and skeleton which transmit muscles, tendons and other structures. The honeycomb pattern of these compartments constitutes the palmar shock absorption system. The soft padded parts of the hand are able to conform to the contours of objects which are grasped, and this permits better interpretation of sensation and better grip.

The hand must also resist tensile loading. Tendons and ligaments are particularly suitable for resisting such forces but many other parts of the fascial continuum, e.g. the anchorage system of the palm, also play a major role in resisting ‘pulling’ forces.

Anchorage

Skin is retained by fascial ligaments which allow the hand to flex while retaining the skin in position. Skin folds at palmar and digital creases possess few deep-anchoring fibres. However, the skin on either side of the crease lines contains deep anchorage ligaments, and these allow the unanchored skin between them to fold in a repetitive pattern. The palmar creases have been described as skin ‘joints’. Fascial anchors may be vertical (perpendicular to the palm), e.g. in the midpalm where scattered vertical fibres run from the dermis down into the depths of the hand; horizontal (in the
plane of the palm); or oblique to the skin surface.

The insertion of the longitudinal (pretendinous) fibres of the palmar aponeurosis is an example of a well-developed horizontal anchorage system. The most superficial longitudinal fibres insert into the dermis of the distal palm. This arrangement resists horizontal shearing force in gripping tasks, e.g. holding a golf club, where it prevents distal skin slippage or degloving of the palm on striking the golf ball. The characteristic blisters on the palms of those unaccustomed to such sports map out the sites of the skin anchorage points. This anchorage system can be demonstrated by flexing the palm until the skin of the distal palm folds loosely. An attempt to pull the loose skin distally will reveal the anchoring longitudinal fibres of the palmar aponeurosis.

Oblique anchors occur in the fingers where Cleland's ligaments tether the skin of the proximal and middle segments of the digits to the region of the proximal interphalangeal joints.

**Binding**

Transversely orientated fascial structures help to maintain the transverse arch of the hand by 'binding' the underlying skeletal structures or the tendon sheaths.

**Limiting or tethering**

Joint motion is limited not only by joint ligamentous action, but also in some cases by skin tightness. Skin in the interdigital webs is generally reinforced by fascial ligamentous fibres which run just beneath the dermis in a direction which resists stretch: they are well developed in the thumb web.

**Lubrication**

There are many other gliding planes, e.g. between periosteum and the extensor apparatus, and between the latter and the skin, on the dorsum of the digits. The flexor tendon sheaths possess low friction and are lubricated by synovial fluid.

**Vascular protection and pumping action**

The blood vessels of the palm are surrounded by a cuff of tough fascia or by a fatty pad. When the hand is compressed, as in gripping, these relatively incompressible fascial structures function as a venous pumping mechanism to assist return of blood from the limb. In contrast, large capacitance veins on the dorsum of the hand lie in gliding skin, surrounded by loose areolar tissue, which allows venous dilatation.

**Framework for muscle attachments**

Many of the small muscles of the hand are attached to the fascial skeleton, at least in part, e.g. abductor pollicis brevis, palmaris longus. The fascial framework can be visualized as a harness by which muscles can act on the underlying skeleton, e.g. the metacarpophalangeal joint is moved by a ring of fascial and ligamentous structures that surround the joint and to which tendons are attached.

**Digital and palmar spaces**
There are many potential spaces within the hand, often with ill-defined margins.

The nail fold is a ‘U-shaped’ space made up of the eponychium and the lateral nail fold. The apical spaces at the tip of the finger are formed by the fibrous attachments of the distal phalanx to the tip of the digital pulp skin. The digital pulp spaces are confined compartments bounded by the digital creases which overlie the joints, and are attached to the underlying pulleys. The synovial flexor tendon sheaths are described on page 879. The web space is bounded distally by the skin and natatory ligament, by the deep transverse metacarpal ligament posteriorly, and by the deep attachments of the palmar fascia, together with their lateral attachments to the tendon sheaths proximally. The deep palmar space is a complex three-dimensional space limited proximally by the carpal tunnel. It lies deep to the palmar aponeurosis, between the radial and ulnar condensations of vertical fibres which connect the palmar aponeurosis to the thenar and hypothenar eminences. Partitions that pass deeply from the longitudinal bands of the palmar aponeurosis form eight narrow compartments: four contain the digital flexor tendons and four contain the lumbricals and the neurovascular bundles.

Infections of the hand

The spaces of the hand limit the spread of infection. Infections in the digit can occur in the nail fold (paronychia), the apical spaces at the very tip of the finger, the distal pulps (a felon) and the flexor sheaths. Anatomically, because the flexor synovial sheath of the thumb and the little finger are continuous throughout the palm, they have the potential to spread infection to the palm and so communicate with other sheaths within the carpal tunnel. Pus can certainly spread proximally within flexor tendon sheaths, but from a clinical point of view it is as disastrous in those digits whose sheaths do not communicate with the carpal tunnel sheaths (index, middle, ring) as it is in those that do (thumb, little finger). It is preferable, therefore, to know the structures rather than the potential spaces between them. Deep infections in the palm are usually not confined to any particular space.
BONE

The skeleton of the hand consists of the carpus, metacarpus and the phalanges. In the following description, proximal and distal are used in preference to superior and inferior, and palmar and dorsal, rather than anterior and posterior.

CARPAL BONES

The carpus contains eight bones: four each in proximal and distal rows (Fig. 50.5 and Fig. 50.6). In radial (lateral) to ulnar (medial) order, the scaphoid, lunate, triquetrum and pisiform make up the proximal row, and the trapezium, trapezoid, capitate and hamate make up the distal row. The pisiform articulates with the palmar surface of the triquetrum, and is thus separated from the other carpal bones, all of which articulate with their neighbours. The other three proximal bones form an arch which is proximally convex, and which articulates with the radius and articular disc of the distal radio-ulnar joint. The concavity of the arch is a distal recess embracing, proximally, the projecting aspects of the capitate and hamate. The two rows of carpal bones are thus mutually and firmly adapted without any loss of movement.

**Fig. 50.5** A. Palmar aspect of the carpal and metacarpal bones of the left hand. Muscle attachments, except for the dorsal interossei, are shown in B.
The dorsal carpal surface is convex. The palmar surface forms a deeply concave carpal groove, accentuated by the palmar projection of the radial (lateral) and ulnar (medial) borders. The ulnar projection is formed by the pisiform and the hamulus (hook), an unciform palmar process of the hamate. The pisiform is at the proximal border of the hypothenar eminence, on the ulnar side of the palm, and it is easily felt in front of the triquetrum. The hamulus is concave in a radial direction, its tip is palpable 2.5 cm distal to the pisiform, in line with the radial border of the ring finger. The superficial division of the ulnar nerve can be rolled on it. The radial border of the carpal groove is formed by the tubercles of the scaphoid and trapezium. The former is distal on the anterior scaphoid surface and palpable (sometimes also visible) as a small medial knob at the proximal border of the palmar thenar eminence, radial to the tendon of flexor carpi radialis. The tubercle of the trapezium is a vertically rounded ridge on the anterior surface of the bone, slightly hollow medially and just distal and radial to the scaphoid tubercle: it is difficult to palpate. (Both the scaphoid and trapezium may be grasped individually, and moved passively, by firm pressure between an opposed index finger and thumb applied to the palmar surface and ‘anatomical snuff-box’ simultaneously.) The carpal groove is made into an osseofibrous carpal tunnel by a fibrous retinaculum attached to its margins. The tunnel carries flexor tendons and the median nerve into the hand. The retinaculum strengthens the carpus and augments flexor efficiency. Radiocarpal, intercarpal and carpometacarpal ligaments are attached to the palmar and dorsal surfaces of all of the carpal bones, except the triquetrum and pisiform.

**Individual carpal bones**

**Scaphoid**

The scaphoid is the largest element in the proximal carpal row (Fig. 50.7A). It has a long axis which is distal, radial and slightly palmar in direction. A round tubercle on the distolateral part of its palmar surface is directed anterolaterally (Fig. 50.5), and provides an attachment for the flexor retinaculum and abductor pollicis brevis: it is crossed by the tendon of flexor carpi radialis. The rough dorsal surface is slightly grooved, narrower than the palmar, and pierced by small nutrient foramina, which are often restricted to the distal half (13%). The radial collateral ligament is attached to the lateral surface, which is also narrow and rough. The remaining surfaces are all
articular. The radial (proximal) surface is convex, proximal and directed proximolaterally; the lunate surface is flat, semilunar, and faces medially; the capitate surface is large, concave and distal, and directed distomedially. The surface for the trapezium and trapezoid is continuous, convex and distal.
Scaphoid bone fractures

The scaphoid is the most frequently fractured carpal bone, typically as a result of a fall onto an outstretched hand. The fracture usually crosses the long axis of the bone. Fractures of its proximal part or its 'waist' may fail to unite because the proximal fragment has lost its blood supply: avascular necrosis of the proximal fragment is then inevitable.

Lunate

The lunate is approximately semilunar and articulates between the scaphoid and triquetrum in the proximal carpal row (Fig. 50.7B). Its rough palmar surface, almost triangular, is larger and wider than the rough dorsal surface. Its smooth convex proximal surface articulates with the radius and the articular disc of the distal radio-ulnar joint. Its narrow lateral surface bears a flat semilunar facet for the scaphoid. The medial surface, almost square, articulates with the triquetrum and is separated from the distal surface by a curved ridge, usually somewhat concave for articulation with the edge of the hamate in adduction (Fig. 50.7B, left). The distal surface is deeply concave to fit the medial part of the head of the capitate.

Triquetrum

The triquetrum is somewhat pyramidal and bears an oval isolated facet for articulation with the pisiform on its distal palmar surface (Fig. 50.7C). Its medial and dorsal surfaces are confluent, and marked distally by the attachment of the ulnar collateral ligament, but smooth proximally to receive the articular disc of the distal radio-ulnar joint in full adduction. The hamate surface, lateral and distal, is concavoconvex, broad proximally, narrow distally. The lunate surface, almost square, is proximal and lateral.

Pisiform

The pisiform is shaped like a pea, with a distolateral long axis (Fig. 50.7D). It bears a dorsal flat articular facet for the triquetrum. The tendon of flexor carpi ulnaris and the distal continuations of the tendon, the pisometacarpal and pisohamate ligaments, are
all attached to the palmar non-articular area, which surrounds and projects distal to the articular surface: the pisiform therefore has attributes of a sesamoid bone.

_Trapezium_

The trapezium has a tubercle and groove on its rough palmar surface (Fig. 50.7E). The groove, which is medial, contains the tendon of flexor carpi radialis, and two layers of the flexor retinaculum are attached to its margins. The tubercle is obscured by the thenar muscles which are attached to it (opponens pollicis, flexor pollicis brevis and abductor pollicis brevis) (Fig. 50.5B). The elongated, rough dorsal surface is related to the radial artery. The large lateral surface is rough for attachment of the radial collateral ligament and capsular ligament of the thumb carpometacarpal joint. A large sellar surface faces distolaterally and articulates with the base of the first metacarpal. Most distally it projects between the bases of the first and second metacarpal bones and carries a small, quadrilateral, distomedially directed facet which articulates with the base of the second metacarpal. The large medial surface is gently concave for articulation with the trapezoid. The proximal surface is a small, slightly concave facet for articulation with the scaphoid. Its ridge, or ‘summit’, fits the concavity of the first metacarpal base, and extends in a palmar and lateral direction, at an angle of approximately 60° with the plane of the second and third metacarpals. Abduction and adduction occur in the plane of the ridge, which is shorter than the corresponding metacarpal groove. Their contours vary reciprocally: they are more curved near the second metacarpal base, whereas the radius of curvature is longer further away from this site. The two surfaces are not completely congruent, and the area of close contact probably moves towards the palm in adduction and dorsally in abduction. While the axis of flexion/extension passes through the trapezium, that for adduction/abduction is in the metacarpal base. Flexion is accompanied by medial rotation, and extension by lateral rotation (p. 875).

_Trapezoid_

The trapezoid is small and irregular. It has a rough palmar surface which is narrower and smaller than its rough dorsal surface: the former invades the lateral aspect (Fig. 50.7F). The distal surface, which articulates with the grooved base of the second metacarpal, is triangular, convex transversely and concave at right angles to this. The medial surface articulates by a concave facet with the distal part of the capitate, the lateral surface articulates with the trapezium, and the proximal surface articulates with the scaphoid.

_Capitate_

The capitate is the central and largest carpal bone. It articulates with the base of the third metacarpal via its triangular distal concavoconvex surface (Fig. 50.7G). Its lateral border is a concave strip for articulation with the medial side of the base of the second metacarpal. Its dorsomedial angle usually bears a facet for articulation with the base of the fourth metacarpal. The head projects into the concavity formed by the lunate and scaphoid: the proximal surface articulates with the lunate, and the lateral surface with the scaphoid. The facets for the scaphoid and trapezoid, though usually continuous on the distolateral surface, may be separated by a rough interval. The medial surface bears a large facet for articulation with the hamate, which is deeper proximally where it is partly non-articular. Palmar and dorsal surfaces are roughened.
for carpal ligaments, the dorsal being the larger.

Hamate

The hamate is cuneiform and bears an unciform hamulus (hook) which projects from the distal part of its rough palmar surface. The hamulus is curved with a lateral concavity and its tip inclines laterally, contributing to the medial wall of the carpal tunnel (Fig. 50.7H). The flexor retinaculum is attached to the apex of the hamulus. Distally, on the hamular base, a slight transverse groove may be in contact with the terminal deep branch of the ulnar nerve. The remaining palmar surface, like the dorsal, is roughened for attachment of ligaments. A faint ridge divides the distal surface into a smaller lateral facet which articulates with the base of the fourth metacarpal base, and a medial facet for articulation with the base of the fifth. The proximal surface, the thin margin of the wedge, usually bears a narrow facet which contacts the lunate in adduction. The medial surface is a broad strip, convex proximally, concave distally, which articulates with the triquetrum: distally a narrow medial strip is non-articular. The lateral surface articulates with the capitate by a facet covering all but its distal palmar angle.

Ossification

Carpal bones are cartilaginous at birth, although ossification may have started in the capitate and hamate. Each carpal bone is ossified from one centre, capitate first, and pisiform last: the order in the others varies (Fig. 50.8, Fig. 5.9, Fig. 5.10, Fig. 5.11, Fig. 50.12). The capitate begins to ossify in the second month, the hamate at the end of the third month, the triquetrum in the third year, the lunate, scaphoid, trapezium and trapezoid in the fourth year in females and fifth year in males. The pisiform begins to ossify in the ninth or tenth year in females, and the twelfth in males. The order varies according to sex, nutrition and, possibly, race. Occasionally an os centrale occurs between the scaphoid, trapezoid and capitate bones: during the second prenatal month it is a cartilaginous nodule which usually fuses with the scaphoid. Occasionally, lunate and triquetral elements may fuse. Other fusions and accessory ossicles have also been described.
Fig. 50.8 Radiograph of a hand at 2½ years (male), dorsopalmar projection. Note early stages of ossification in the epiphyses at the proximal ends of the phalanges and first metacarpal; at the distal ends of the remaining metacarpals and radius; in the capitate, hamate and lunate. Typically, the centre for the lunate is preceded by the centre for the triquetrum. Compare with Figs 50.9 and 50.10.
Fig. 50.12. The bones of the hand of a child, indicating the general plan of ossification.
METACARPALS

The metacarpus consists of five metacarpal bones, conventionally numbered in radio-ulnar order. These are miniature long bones, with a distal head, shaft and expanded base. The rounded heads articulate with the proximal phalanges. Their articular surfaces are convex, although less so transversely, and extend further on the palmar surfaces, especially at their margins. The knuckles are produced by the metacarpal heads. The metacarpal bases articulate with the distal carpal row and with each other, except the first and second. The shafts have longitudinally concave palmar surfaces, which form hollows for the palmar muscles. Their dorsal surfaces bear a distal triangular area, which is continued proximally as a round ridge. These flat areas are palpable proximal to the knuckles.

The medial four metacarpals are sometimes described as parallel; strictly speaking, they diverge somewhat, and radiate gently proximodistally. However, the first metacarpal, relative to the others, is more anterior and rotated medially on its axis through 90°, so that its morphologically dorsal surface is lateral, its radial border palmar, its palmar surface medial, and its ulnar border dorsal. Hence the thumb flexes medially across the palm and can be rotated into opposition with each finger. Opposition depends on medial rotation and is the prime factor in manual dexterity: when an object is grasped, fingers and thumb encircle it from opposite sides, greatly increasing the power and skill of the grip.

Individual metacarpal bones

First metacarpal

The first metacarpal is short and thick (Fig. 50.13A). Its dorsal (lateral) surface can be felt to face laterally; its long axis diverges distolaterally from its neighbour. The shaft is flattened, dorsally broad and transversely convex. The palmar (medial) surface is longitudinally concave and divided by a ridge into a larger lateral (anterior) and smaller medial (posterior) part. Opponens pollicis is attached to the radial border and adjoining palmar surface; the first dorsal interosseous muscle (radial head) is attached to its ulnar border and adjacent palmar surface. The base is concavoconvex and articulates with the trapezium. Abductor pollicis longus is attached on its lateral (palmar) side, the first palmar interosseous muscle to its ulnar side. The head is less convex than in other metacarpals and is transversely broad. Sesamoid bones glide on radial and ulnar articular eminences on its palmar aspect.
The second metacarpal has the longest shaft and largest base (Fig. 50.13B). The latter is grooved in a dorsopalmar direction for articulation with the trapezoid. Medial to the groove a deep ridge articulates with the capitate; laterally, nearer the dorsal surface of the base, there is a quadrilateral facet for articulation with the trapezium, and just dorsal to this facet a rough impression marks the attachment of extensor carpi radialis longus. On the palmar surface a small tubercle or ridge receives flexor carpi radialis. The medial side of the base articulates with that of the third metacarpal by a long facet, centrally narrowed. The shaft is prismatic in section and longitudinally curved, convex dorsally, concave towards the palm. Its dorsal surface is distally broad but proximally narrows to a ridge which is covered by extensor tendons of the index finger. Its converging borders begin at the tubercles, one on each side of its head for the attachment of collateral ligaments. Proximally the lateral surface inclines dorsally for the ulnar head of the first dorsal interosseous. The medial surface inclines similarly, and is divided by a faint ridge into a palmar strip for attachment of the second palmar interosseous, and a dorsal strip for attachment of the radial head of the second dorsal interosseous.

Third metacarpal

The third metacarpal has a short styloid process, projecting proximally from the radial side of the dorsal surface (Fig. 50.13C). Its base articulates with the capitate by a facet anteriorly convex but dorsally concave where it invades the styloid process on the lateral aspect of its base. A strip-like facet, constricted centrally, articulates with
the bases of the second metacarpal (laterally) and the fourth metacarpal (medially),
the latter by two oval facets. The palmar facet may be absent; less frequently the
facets are connected proximally by a narrow bridge. The palmar surface of the base
receives a slip from the tendon of flexor carpi radialis; extensor carpi radialis brevis is
attached to its dorsal surface, beyond the styloid process. The shaft resembles that of
the second metacarpal. The ulnar head of the second dorsal interosseous is attached
to its lateral surface; the radial head of the third dorsal interosseous is attached to its
medial surface, and the transverse head of adductor pollicis is attached to the
intervening palmar ridge in its distal two-thirds. Its dorsal surface is covered by the
extensor tendon.

Fourth metacarpal

The fourth metacarpal is shorter and thinner than the second and third (Fig. 50.13D).
On its base it displays two lateral oval facets for articulation with the base of the third
metacarpal; the dorsal is usually larger and proximally in contact with the capitate. A
single medial elongated facet is for articulation with the base of the fifth metacarpal.
The quadrangular proximal surface articulates with the hamate, and is anteriorly
convex, dorsally concave. The shaft is like the second, but a faint ridge on its lateral
surface separates the attachments of the third palmar interosseous and the ulnar
head of the third dorsal interosseous. The radial head of the fourth dorsal
interosseous is attached to the medial surface.

Fifth metacarpal

The fifth metacarpal (Fig. 50.13E) differs in its medial basal surface, which is non-
articular and bears a tubercle for extensor carpi ulnaris. The lateral basal surface is a
facet, transversely concave, convex from palm to dorsum, for articulation with the
hamate. A lateral strip articulates with the base of the fourth metacarpal. The shaft
bears a triangular dorsal area which almost reaches the base; the lateral surface
inclines dorsally only at its proximal end. Opponens digiti minimi is attached to the
medial surface. The lateral surface is divided by a ridge, which is sometimes sharp,
into a palmar strip for the attachment of the fourth palmar interosseous and a dorsal
strip for the ulnar part of the fourth dorsal interosseous.

Ossification

Each metacarpal ossifies from a primary centre for the shaft and a secondary centre
which is in the base of the first metacarpal and in the heads of the other four (Figs
50.8–50.11). Ossification begins in the midshaft about the ninth week. Centres for the
second to fifth metacarpal heads appear in that order in the second year in females,
and between 1½ to 2½ years in males. They unite with the shafts about the 15th or
16th year in females, 18th or 19th in males. The first metacarpal base begins to ossify
late in the second year in females, early in the third year in males, uniting before the
15th year in females and 17th in males. Sometimes the styloid process of the third
metacarpal is a separate ossicle. The thumb metacarpal ossifies like a phalanx, and
some authorities therefore consider that the thumb skeleton consists of three
phalanges. Others believe that the distal phalanx represents fused middle and distal
phalanges, a condition occasionally observed in the fifth toe. When the thumb has
three phalanges, the metacarpal has a distal and a proximal epiphysis. It occasionally
bifurcates distally. When it does, the medial branch has no distal epiphysis and bears
two phalanges, while the lateral branch shows a distal epiphysis, and three phalanges. The existence of only a distal metacarpal epiphysis may be associated with a greater range of movement at the metacarpophalangeal joint. In the thumb, the carpometacarpal joint has the wider range, and the first metacarpal has a basal epiphysis. A distal epiphysis may appear in the first, and a proximal epiphysis in the second, metacarpal.

Fig. 50.9 Radiograph of a hand at 6½ years (male), dorsopalmar projection. Note the more advanced state of the centres of ossification which were already visible in Fig. 50.8, and the appearance of additional centres in the distal ulnar epiphysis and in the triquetrum, scaphoid, trapezium and trapezoid.
Fig. 50.10  Radiograph of a hand at 11 years (female), dorsopalmar projection. Note the maturing shapes of all the ossifications previously seen in Figs 50.8 and 50.9, with the addition of the pisiform.

PHALANGES

There are 14 phalanges, three in each finger, two in the thumb. Each has a head, shaft and proximal base. The shaft tapers distally, its dorsal surface transversely convex. The palmar surface is transversely flat but gently concave anteriorly in its long axis. The bases of the proximal phalanges carry concave, oval facets adapted to the metacarpal heads. Their own heads are smoothly grooved like pulleys and encroach more on to the palmar surfaces. The bases of the middle phalanges carry two concave facets separated by a smooth ridge, conforming to the heads of the proximal phalanges. The bases of the distal phalanges are adapted to the pulley-like heads of the middle phalanges. The heads of the distal phalanges are non-articular and carry a rough, crescentic palmar tuberosity to which the pulps of the fingertips are attached.

Articular ligaments and numerous muscles are attached to the phalanges. A corresponding tendon of flexor digitorum profundus and, on its dorsal surface, extensor digitorum, are attached to the base of each distal phalanx on its palmar surface. A tendon of flexor digitorum superficialis and its fibrous sheath are attached to the sides of a middle phalanx, and a part of extensor digitorum is attached to the base dorsally. A fibrous flexor sheath is attached to the sides of a proximal phalanx, part of the corresponding dorsal interosseous is attached to its base laterally, and another dorsal interosseous is attached medially.

The phalanges of the little finger and the thumb differ. Abductor and flexor digiti minimi are attached to the medial side of the base of the proximal phalanx of the little finger. The tendon of extensor pollicis brevis and the oblique head of adductor pollicis (dorsally), and the oblique and transverse heads of adductor pollicis, sometimes conjoined with the first palmar interosseous (medially), are attached to the base of the proximal pollicial phalanx.

The margins of the proximal pollicial phalanx are not sharp, because the fibrous sheath is less strongly developed than it is in the other digits.

Ossification

Phalanges are ossified from a primary centre for the shaft and a proximal epiphysial centre (Figs 50.8–50.12). Ossification begins prenatally in shafts as follows: distal phalanges in the eighth or ninth week, proximal phalanges in the tenth, middle phalanges in the 11th week or later. Epiphysial centres appear in proximal phalanges early in the second year (females), and later in the same year (males), and in middle and distal phalanges in the second year (females), or third or fourth year (males). All epiphyses unite about the 15th to 16th year in females, and 17th to 18th year in males.
JOINTS

DISTAL RADIO-ULNAR JOINT

The distal radio-ulnar joint is a uniaxial pivot joint (Fig. 50.14).

Articulating surfaces

The articulating surfaces are between the convex distal head of the ulna and the concave ulnar notch of the radius, and are connected by an articular disc.

Fibrous capsule

The fibrous capsule is thicker anteriorly and posteriorly, but the proximal part of the capsule is lax.

Articular disc

The articular disc is fibrocartilaginous (collagen with few elastic fibres in the young) and is triangular, binding the distal ends of the ulna and radius. Its periphery is thicker, its centre sometimes perforated. The disc is attached by a blunt, thick apex to a depression between the ulnar styloid process and distal articular surface, and by its wider thin base to the prominent edge between the ulnar notch and carpal articular surface of the radius. Its margins are united to adjacent carpal ligaments, its surfaces are smooth and concave: the proximal articulates with the ulnar head, the distal is part of the radiocarpal joint, and articulates with the lunate and, when the hand is adducted, the triquetrum. The disc shows age-related degeneration, becoming thinned and ultimately perforated in about half the subjects over the age of 60.

Fig. 50.14 Transverse section through the left wrist at the level of the distal radio-ulnar joint, showing the muscle tendons and their synovial sheaths.
(From Sobotta 2006.)
Synovial membrane

The capsule is lined by synovial membrane which projects proximally between the radius and ulna as a recessus sacciformis in front of the distal part of the interosseous membrane.

Vascular supply and lymphatic drainage

The arterial supply to the distal radio-ulnar joint and disc is mainly derived from the palmar and dorsal branches of the anterior interosseous artery, reinforced by the posterior interosseous and ulnar arteries.

Innervation

The distal radio-ulnar joint is innervated by branches of the anterior and posterior interosseous nerves.

Movements

Movements at the radio-ulnar joint complex pronate and supinate the hand. In pronation the radius, carrying the hand, turns anteromedially and obliquely across the ulna, its proximal end remains lateral, its distal becomes medial. During this action the interosseous membrane becomes spiralled. In supination the radius returns to a position lateral and parallel to the ulna and the interosseous membrane becomes unspiralled. The hand can be turned through 140–150°: with the elbow extended, this can be increased to nearly 360° by humeral rotation and scapular movements. Power is greater in supination, a fact which has affected the design of nuts, bolts and screws, which are tightened by supination in right-handed subjects. Moreover, supination is an antigravity movement with a pendent upper arm and semiflexed forearm; in seizing objects for examination or manipulation, pronation is merely a preliminary and is aided by gravity.

Forearm rotation occurs between the articulation of the head of the ulna and sigmoid notch distally, and the head of the radius and the radial notch of the ulna proximally. These distal and proximal radio-ulnar joints are pivot-type synovial joints: they act as a pair permitting stable rotary motion (pronation 61–66°, supination 70–77°). During rotation, the radius moves around the ulnar head. The axis for pronation and supination is often represented as a line through the centre of the radial head (proximal) and the ulnar attachment of the articular disc (distal). More correctly this is the axis of movement of the radius relative to the ulna and it does not remain stationary. The radial head rotates in the fibro-osseous ring: its distal lower end and articular disc swing round the ulnar head. During rotation of the radial head its proximal surface spins on the humeral capitulum. As the forearm moves from full pronation into supination the ulna translocates medially by 9–10 mm, such that the axis of rotation shifts but still passes through the ulnar head. In addition the sigmoid notch changes its contact position with the ulnar head, lying dorsal proximal in pronation and volar distal in supination. The distal end of the ulna is not stationary during these movements; it moves a variable amount along a curved course, posterolaterally in pronation, anteromedially in supination. The axis of movement, as defined above, is therefore displaced laterally in pronation, medially in supination. Hence the axis for supination and pronation of the whole forearm and hand passes between the bones at both the superior and distal radio-ulnar joints when ulnar
movement is marked, but through the centres of the radial head and ulnar styloid when it is minimal. The axis may be prolonged through any digit, depending on the medial or lateral displacement of the distal end of the ulna. The hand will rotate further than the forearm because of the sliding–rotatory movement which occurs between the carpal bones and the bases of the metacarpals and, to a very minor degree, at the radiocarpal joint.

**Accessory movements**

Accessory movements include anterior and posterior translation of the radial head on the ulnar radial notch, and of the ulnar head likewise on the radial ulnar notch.

**Muscles producing movement**

The muscles producing movements at the distal radio-ulnar joint are as follows.

**Pronation**

Pronator quadratus, aided in rapid movement and against resistance by pronator teres. Gravity also assists.

**Supination**

Supinatus, in slow unresisted movement and extension, assisted by biceps in fast movements in flexion, especially when resisted.

Electromyographic studies have not confirmed activity in brachioradialis during pronation and supination.
RADIOCARPAL (WRIST) JOINT

Articulating surfaces

The radiocarpal joint is a synovial biaxial and ellipsoid joint formed by articulation of the distal end of the radius and the triangular fibrocartilage with the scaphoid, lunate and triquetrum (Fig. 50.15 and Fig. 50.16). In the neutral position of the wrist, only the scaphoid and lunate are in contact with the radius and articular disc; the triquetrum comes into apposition with the disc only in full adduction of the wrist joint. The radial articular surface and distal discal surface form an almost elliptical, concave surface with a transverse long axis. The radial surface is bisected by a low ridge into two concavities. A similar ridge usually appears between the medial radial concavity and the concave distal discal surface. The proximal articular surfaces of the scaphoid, lunate and triquetrum, and their interosseous ligaments, form a smooth convex surface which is received into the proximal concavity.

Fig. 50.15 Joints and ligaments of the left hand. A, Palmar aspect. B, Dorsal aspect.
Fibrous capsule

The fibrous capsule is lined by synovial membrane which is usually separate from that of the distal radio-ulnar and intercarpal joints. A protruding prestyloid recess (recessus sacciformis), anterior to the articular disc, is present and ascends close to the styloid process. The recess is bounded distally by a fibrocartilaginous meniscus, which projects from the ulnar collateral ligament between the tip of the ulnar styloid process and the triquetrum; both are clothed with hyaline articular cartilage. The meniscus may ossify. The capsule is strengthened by palmar radiocarpal and ulnocarpal, dorsal radiocarpal and radial and ulnar collateral ligaments.

Synovial membrane

The synovial membrane lines the fibrous capsule.

Vascular supply

The radiocarpal joint is supplied by branches of the anterior interosseous artery, anterior and posterior carpal branches of the radial and ulnar arteries, palmar and dorsal metacarpal arteries and recurrent rami of the deep palmar arch.

Innervation

The radiocarpal joint is innervated by the anterior and posterior interosseous nerves.
with contributions from the median, ulnar and radial nerves.

**Muscles producing movement**

Movements accompany those of the intercarpal and midcarpal joints and are described on page 871.
CARPAL JOINTS

The intercarpal joints interconnect the carpal bones. They may be summarized as the joints between the proximal and distal rows of carpal bones, and the midcarpal joint, a complex joint between the rows.

Carpal bones are connected by an extensive array of ligaments, not all of which are specifically named. The flexor retinaculum is an accessory intercarpal ligament. Articular surfaces are either sellar, ellipsoid or spheroidal.

Joints of the proximal carpal row

Joints of the proximal carpal row are between the scaphoid, lunate and triquetrum. In addition, the pisiform articulates with the palmar surface of the triquetrum at a small, oval, almost flat, synovial pisotriquetral joint.

A thin capsule surrounds the joint. The synovial cavity is usually separate but may communicate with that of the radiocarpal joint.

Joints of the distal carpal row

Joints of the distal carpal row are between the trapezium, trapezoid, capitate and hamate. There is virtually no movement at these joints.

Midcarpal joint

The midcarpal joint, between the scaphoid, lunate and triquetrum (proximally) and trapezium, trapezoid, capitate and hamate (distally) is a compound articulation that may be divided descriptively into medial and lateral parts. Throughout most of the medial compartment the convexity formed by the head of the capitate and hamate articulates with a reciprocal concavity formed by the scaphoid, lunate and much of the triquetrum. However, most medially the curvatures are reversed, forming a compound sellar joint. In the lateral compartment the trapezium and trapezoid articulate with the scaphoid, forming a second compound articulation, often said to be plane, but which is also sellar.

Carpal synovial membrane

The carpal synovial membrane is most extensive, and lines an irregular articular cavity. Its proximal part is between the distal surfaces of the scaphoid, lunate and triquetrum and the proximal surfaces of the second carpal row. It has proximal prolongations between the scaphoid and lunate, and lunate and triquetrum, and three distal prolongations between the four bones of the second row. The absence of an interosseous ligament means that the prolongation between the trapezium and trapezoid and/or between the trapezoid and capitate is often continuous with corresponding carpometacarpal joints, variably from the second to the fifth, or often the second and third only. In the latter case, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial membrane and the carpometacarpal interosseous ligament is interposed. Synovial cavities of carpometacarpal joints are prolonged slightly between the metacarpal bases. The synovial joint between the pisiform and triquetrum is usually isolated.
Vascular supply

The carpal joints are supplied by the posterior carpal branches of the radial and ulnar arteries and by the anterior interosseous artery.

Innervation

Precise details about innervation of the carpal joints are lacking. They appear to be innervated by small branches from the deep terminal branch of the ulnar nerve, the median nerve and its anterior interosseous branch, the superficial radial nerve and the posterior interosseous branch of the radial nerve.

Wrist ligaments

Wrist ligaments situated between the fibrous and synovial layers of the wrist joint are termed intracapsular, while those lying superficial to the fibrous layer are extracapsular. Almost all ligaments of the wrist actually lie within the joint capsule and the only exceptions are the flexor and extensor retinaculae and the pisotriquetral ligament. The intracapsular ligaments appear to blend one into another and the edges of the ligaments may not be distinct or discrete.

The ligaments are further classified into extrinsic and intrinsic named ligaments. In addition there are superficial and deep parts to some of the extrinsic ligaments; the latter are identifiable at wrist arthroscopy, the former are not.

It is important to appreciate that the wrist ligaments are named from proximal to distal and from radial to ulnar. Thus a ligament passing between the capitate, scaphoid and radius is called the radioscapophocapitate ligament.

Extrinsic ligaments

Extrinsic ligaments connect the carpus with the forearm bones. The extrinsic ligaments as a group tend to be longer than the intrinsic ligaments. They are approximately one-third as strong but easier to repair following rupture.

Extrinsic palmar carpal ligaments

When the synovial lining of the carpal tunnel is dissected away, two V-shaped ligamentous bands are visible with their apices lying distally (Fig. 50.15A). The limbs of the ‘V’ take origin from the radius and ulna respectively: the apex of one ‘V’ attaches to the distal row and that of the second ‘V’ to the proximal row.

Radioscapophocapitate ligament

The radioscapophocapitate ligament originates from the radial styloid and the palmar lip of the radius. It courses distally and is then described by some authors as having three parts. The first is the most radial and inserts onto the lateral aspect of the waist of the scaphoid (radial collateral ligament). The second continues as part of the distal ‘V’ and inserts onto the distal pole of the scaphoid. The third passes over the proximal pole of the scaphoid towards the midcarpus and blends with the fibres originating from the ulnar side – part of the triangular fibrocartilage complex – to form the arcuate ligament over the palmar aspect of the capitate. A few of the fibres of the radioscapophocapitate ligament attach to the body of the capitate. There is a discrete
interval between the inferior margin of this ligament and the palmar horn of the lunate which is known as the space of Poirier.

**Long radiolunate ligament**

The long radiolunate ligament takes origin adjacent to the radioscapohcapitate ligament on the palmar lip of the radius. It passes over and supports the proximal pole of the scaphoid before inserting into the palmar horn of the lunate. This ligament is discrete from the radioscapohcapitate ligament and the visible separation is known as the interligamentous sulcus (continuous with the space of Poirier).

**Radioscapholunate (ligament of Testut)**

Histological studies have shown the radioscapholunate ligament is not a true ligament because it contains neurovascular structures which supply the scapholunate interosseous membrane and is covered by a thick synovial lining. However it a visible landmark inside the wrist joint when undertaking wrist arthroscopy.

**Short radiolunate ligament**

The short radiolunate ligament is part of the proximal 'V'. It arises from the palmar lip of the lunate fossa of the radius and passes directly to the palmar horn of the lunate. To the ulnar side its fibres blend with those of the palmar triangular fibrocartilage complex as these also pass to their insertion on the lunate. This ligament contributes to the stability of the lunate.

**Ulnolunate ligament**

The ulnolunate ligament originates from the palmar aspect of the ulna adjacent to the short radiolunate ligament and inserts onto the palmar horn of the lunate. Part of this fibre complex arches radially and blends with part of the radioscapohcapitate complex, forming the arcuate ligament.

**Ulnotriquetral (ulnar collateral) ligament**

The ulnotriquetral ligament arises from the palmar aspect of the ulna and inserts into the medial aspect of the triquetrum. It continues distally to a further attachment to the medial aspect of the hamate. It is generally thought that the ulnolunate and ulnotriquetral ligaments also take some origin from the marginal ligament of the triangular fibrocartilage complex.

**Extrinsic dorsal carpal ligaments**

The dorsal wrist ligaments are comparatively thin. They are reinforced by the floor and septa of the fibrous tunnels for the six dorsal compartments. The extrinsic dorsal carpal ligaments and the intrinsic dorsal intercarpal ligaments have a ‘Z-shaped’ configuration (Fig. 50.15B). The pattern and shape of these ligaments is utilized in one surgical approach to the dorsum of the wrist joint where incisions are oriented parallel with the ligaments: this reduces scarring and restriction of subsequent motion caused by the arthrotomy.

**Dorsal radiolunotriquetral ligament**
The dorsal radiolunotriquetral ligament is a true intracapsular ligament. It is the only extrinsic ligament on the dorsum of the carpus and has superficial and deep components. The superficial part connects the radius and triquetrum, and the deep part connects the radius, lunate and triquetrum. The two components are inseparable. The wide superficial component arises from the dorsal margin of the distal radius and courses ulnarily to insert on the dorsal edge of the triquetrum. The deep component takes a narrower origin from the ulnar aspect of the distal dorsal radius and passes in an ulnar direction to attach to part of the lunotriquetral articulation and the intrinsic lunotriquetral ligament.

Intrinsic ligaments

Intrinsic ligaments of the wrist are attached to carpal bones. They are stronger and shorter than extrinsic ligaments and are connected with the extrinsic ligament complexes by interdigitating fibres. Rupture of one or more intrinsic ligaments frequently leads to a clinical instability of the carpus. The intrinsic ligaments are subdivided into ligaments which connect the carpal bones of the proximal and distal rows respectively and ligaments which connect the rows by crossing over the midcarpal joint.

Proximal row interosseous ligaments

The scapholunate and lunotriquetral ligaments are clinically and biomechanically important structures. In the sagittal plane they have an approximately horseshoe-shape configuration with palmar, midcarpal and dorsal components. The scapholunate ligament contains short transverse fibres connecting the dorsal aspect of the respective bones and more obliquely oriented fibres connecting the palmar aspect. The functional significance of this arrangement is that the tighter dorsal component of the ligament acts as a hinge facilitating flexion and extension of the scaphoid: these movements are important to carpal mechanics. The ligament continues on its midcarpal section as an interosseous membrane. The lunotriquetral ligament has similar dorsal, midcarpal interosseous and palmar components, but the fibres of the dorsal and palmar components are similarly rather than differentially oriented, which precludes the same pattern of preferential movement as occurs between the lunate and scaphoid. The interosseous membranes of the scapholunate and lunotriquetral ligaments separate the midcarpal from the radiocarpal joint spaces. Dye injected into one of these joint spaces which leaks to the other denotes a tear of one of these ligaments.

Distal row interosseous ligaments

The distal row interosseous ligaments are powerful ligaments between the capitate, hamate, trapezium and trapezoid, with an important stabilizing function for the distal carpal row. They have superficial and deep components, and unlike the ligaments of the proximal row, are seldom torn.

Palmar midcarpal ligaments

Anterolaterally lies the fan-shaped palmar scaphocapitate – trapezoid ligament which originates from the scaphoid tuberosity and is thought to be an important stabilizer of the scaphoid. This ligament may be subdivided into two parts known as the scaphotrapeziotrapezoidal ligament (having the attachments as its name suggests)
and a more ulnar component known as the scaphocapitate ligament. The triquetrohamate and triquetrocapitate ligaments lie towards the ulnar side of the carpus.

**Dorsal midcarpal ligaments**

The dorsal intercarpal ligament assists in stabilization of the proximal carpal row. It arises from the trapezoid and distal pole of scaphoid, and passes across the dorsal horn of the lunate to be attached to the triquetrum. The ligament forms the floor of the fourth and fifth extensor compartments. On the radial side is the lateral scaphotrapeziotrapezoidal ligament which acts as a stabilizer of the scaphoid and trapezium.

**Triangular fibrocartilage complex (TFCC) and distal radio-ulnar ligaments**

The triangular fibrocartilage complex (TFCC) is a ligamentous and cartilaginous structure which suspends the distal radius and ulnar carpus from the distal ulna. The TFCC stabilizes the ulnocarpal and radio-ulnar joints, transmits and distributes load from the carpus to the ulna, and facilitates complex movements at the wrist (Fig. 50.17). By definition, it is made up of the cartilaginous disc, the meniscus homologue (an embryological remnant of the ‘ulnar’ wrist that is only occasionally present), volar and dorsal distal radio-ulnar ligaments, ulnar collateral ligament, floor of extensor carpi ulnaris subsheath, ulnolunate and ulnotriquetral ligaments. The triangular fibrocartilage proper (TFC) is a biconcave body composed of chondroid fibrocartilage. It extends across the dome of the ulnar head and varies between 2 and 5 mm in thickness.

![Fig. 50.17](image) Representation of the manner in which the radius moves around the ulna during forearm rotation. The curvature of the shaft of the radius is important in facilitating this movement. The axis of forearm rotation passes through the head of
From its distal aspect, the TFCC resembles a hammock supporting the ulnar carpus with the disc proper as the base of the hammock. From the proximal side, the TFCC appears in the shape of a fan extending from the fovea of the ulna along either side of the sigmoid notch. This fan-shaped structure is divided into dorsal, central and palmar portions where the central portion is the triangular fibrocartilage and the peripheral margins are thick lamellar collagen, structurally adapted to tensile loading and known as the distal (palmar and dorsal) radio-ulnar ligaments. In keeping with other extrinsic ligaments of the wrist joint proper there are thought to be superficial and deep components of the distal radio-ulnar ligaments which act as a functional couple stabilizing the rotation of the ulnar head on the sigmoid notch of the radius.

Stability of the distal radio-ulnar joint during forearm rotation is conferred by the TFCC complex, dorsal and volar distal radio-ulnar ligaments, interosseous membrane and subsheath of the extensor carpi ulnaris tendon (floor of sixth dorsal extensor compartment).
**COORDINATED MOVEMENTS AND LOAD-BEARING AT THE WRIST JOINT**

**Wrist movements**

The movements at the radiocarpal and intercarpal joints are considered together since they are both involved in all movements as well as being acted upon by the same muscles. Active movements are flexion (85°), extension (85°), adduction or ulnar deviation (45°), abduction or radial deviation (15°) and circumduction (all movements are approximate).

The range of flexion is greater at the radiocarpal joint, while in extension there is more movement at the midcarpal joint (Fig. 50.18). Hence the proximal surfaces extend further posteriorly on the lunate and scaphoid bones. These movements are limited chiefly by antagonistic muscles, and therefore the range of flexion is perceptibly diminished when the fingers are flexed, due to increased tension in the extensors. Only when the joints are forced to the limits of flexion or extension are the dorsal or palmar ligaments fully stretched (but see below).
Adduction of the hand is considerably greater than abduction, perhaps due to the more proximal site of the ulnar styloid process. Most adduction occurs at the radiocarpal joint. The lunate articulates with both the radius and articular disc when the hand is in the midposition, but in adduction it articulates solely with the radius, and the triquetrum now comes into contact with the articular disc (Fig. 50.19A). Much of the proximal articular surface of the scaphoid becomes subcapsular beneath the radial collateral ligament and forms a smooth, convex, palpable prominence in the floor of the ‘anatomical snuff-box’.
Abduction from the neutral position occurs at the midcarpal joint, the proximal carpal row not moving. Radiographs of abducted hands show that the capitate rotates round an anteroposterior axis so that its head passes medially and the hamate conforms to this: the distance between the lunate and the apex of the hamate is increased (Fig. 50.19B). The scaphoid rotates around a transverse axis, and its proximal articular surface moves away from the capsule to articulate solely with the radius. Movements
are limited by antagonistic muscles and, at extremes, by the carpal collateral ligaments.

Circumduction of the hand is not rotatory, but involves successive flexion, adduction, extension and abduction or vice versa.

**Muscles producing movements**

**Flexion**

Flexores carpi radialis and ulnaris and palmaris longus, assisted by flexores digitorum superficialis and profundus and flexor pollicis longus.

**Extension**

Extensores carpi radialis longus, brevis and ulnaris, assisted by extensores digitorum, digiti minimi, indicis and pollicis longus.

**Adduction**

Flexor and extensor carpi ulnaris.

**Abduction**

Flexor carpi radialis, extensores carpi radialis longus and brevis, with abductor pollicis longus and extensor pollicis brevis.

**Integrated model of wrist movement (carpal kinematics)**

The proximal row (scaphoid, lunate and triquetrum) is an intercalated segment: no tendons insert onto the bones of the row. It is inherently unstable and controlled by specific retaining and gliding ligaments. Its relative position is determined by the spatial configurations of the radius, triangular fibrocartilage complex (TFCC) and ulna on one side, and the rigid distal carpal row on the other. The proximal carpal row is subject to two opposing moments: the scaphoid straddles the proximal and distal rows and tends to rotate the proximal row into flexion under axial load and radial deviation. At the same time there is a force tending to extend the proximal row which is initiated by the distal row and transmitted via the midcarpal ligaments to the triquetrum (Fig. 50.20). Stability of the midcarpal joint is thus ensured during both movement and loading.
The balance of rotatory moments occurring during axial loading are explained in this series of sagittal sections of the wrist. A, The scaphoid tends to move into flexion with axial loading and is simultaneously constrained palmarly by the scaphotrapeziotrapezoidal ligaments and dorsally by the scapholunate ligament. B, The lunate tends to follow the scaphoid restrained only by the dorsal radiolunate ligament. C, The triquetrum tends to flex along with the two other bones of the proximal carpal row and is constrained palmarly by the triquetrohamate and triquetrocapitate ligaments and dorsally by the radiotriquetral ligament.

The distal carpal row (trapezium, trapezoid, capitate and hamate) can be regarded as one rigid structure tightly bound together. The scaphoid bridges the proximal and distal carpal rows and provides a functional couple between the two.

The carpus was originally thought to move simply as proximal and distal rows (row or rigid body theory). According to this view, during the composite movement of wrist flexion and extension, approximately two-thirds of movement occurs at the radiocarpal joint and one-third at the midcarpal joint. The carpus was later judged to move in lateral central and medial columns more than it did in rows, and the radius–lunate–capitate was described as a three-bar linkage system (column theory). This theory was modified to incorporate the specific stabilizing role of the scaphoid as it bridges the proximal and distal rows. A further theory proposed that the bones were linked by their ligaments in a ring configuration, so that any breakage of the key links leads to instability (ring theory). Most recently the ‘four unit’ theory suggests that the distal carpal row moves as a single unit, and the scaphoid, lunate and triquetrum move in complex but characteristic relationships which are dependent on the given movement (Fig. 50.21). Clinical observation provides some support for each of these theories.

**Fig. 50.21** Different theories of carpal mechanics. A, Row or rigid body theory; B, central column theory of Navarro; C, ring theory of Taleisnik; D, four-unit concept of Viegas.

**Wrist loading**

Axial loading refers to load or force applied along a line parallel to the long bones of the arm and therefore corresponds to power grip manoeuvres, e.g. clenching the fist. In the normal activities of daily living, loading is usually multiplanar with a combination...
of vectors of force, e.g. grasping an object and then lifting it against gravity with the elbow flexed would engender transverse and axial loading with respect to the long axis of the forearm.

**Force transmission**

**Radiocarpal joint**

The articulation of the carpus with the radius (radiocarpal) and ulna (ulnocarpal) can be described in terms of specific fossae, i.e. the scaphoid and lunate fossae of the radius and the facet formed by the distal aspect of the TFCC. The scaphoid fossa contributes 43%, the lunate fossa 46%, and the TFCC 11%, of the total area of this articulating surface. Under physiological conditions, the contact area between this surface and the proximal carpal row is of the order of 20% of the whole. It varies consistently with position: greater contact is seen in forearm supination, radial deviation and dorsiflexion of the wrist, and lesser contact in forearm pronation, ulnar deviation and palmar flexion of the wrist. Further increase in contact area is seen with axial loading. Maximum contact areas are recorded at 40%. Force across the joint also varies with the position of the forearm and the degree of wrist flexion. For a given load in wrist neutral position, 50% of force passes across the scaphoid fossa, 35% through the lunate fossa, and 15% across the TFCC. With a power grip there is slight ulnar deviation, and the proportion of force passing across the scaphoid and lunate fossae reverses.

**Midcarpal joint**

With the wrist in neutral position, 50–60% of a given load is transmitted from the distal row through the capitate to the scaphoid and lunate. Up to 30% of the load is transmitted via the scaphotrapeziotrapezoid joint, and up to 20% via the hamate-triquetral joint.

**Distal radio-ulnar joint (DRUJ)**

The DRUJ is part of a more complex articulation that includes the proximal radio-ulnar joint and the interosseous membrane. Static axial loading of the wrist increases the contact areas of the joint surfaces of the distal radio-ulnar joint, DRUJ. Force transmitted across the DRUJ also increases with axial loading and varies with position of forearm rotation. It is maximal at 60° supination, when the ulnar head lies most directly under the ulnar-sided carpus, and least in full pronation. It has been shown that with the wrist in neutral position, 70–80% of axial load passes down the radius and 20–30% down the ulna. The proportion of force passing down the ulna varies with increasing load, and changes with position of the hand and carpus relative to the forearm bones. The interosseous membrane between the radius and ulna plays a role in distributing load in the forearm. Distal radio-ulnar joint loading also depends on relative radial and ulnar lengths, i.e. ulnar negative, neutral or positive variance.

**Specific actions**

**Power grip**

There is a predictable pathway of force transmission during axial loading of the hand such as occurs in power grip. During this action the wrist is positioned in mid-
dorsiflexion and the object is tightly gripped. Force is transmitted from the hand and wrist via the radiocarpal joint and TFCC to both bones of the forearm, through the elbow joint to the humerus, and thence via the glenohumeral joint to the pectoral girdle. Dynamic muscle action accounts for transmission of a large part of the force, and a smaller proportion is transmitted through the osseoligamentous structures. The distribution of force between the radius and ulna varies dynamically. It depends on the absolute value of load, degree of forearm rotation, and position of the carpus relative to the forearm.

Hammer action

The action exemplified by hammering, where the wrist alternates between the dorsoradial and the palmar-ulnar position, is an important movement. The reciprocal movement is more constrained and awkward to perform. The former movement is important in a wide variety of activities of daily living. In primates this movement is needed (along with forearm rotation at the distal radio-ulnar joint) for brachiation.

It is believed that load distributes dynamically as the position of the carpus moves relative to the forearm and there are consequent changes in the relative position of the carpal bones.

Wrist instability

During evolution the upper limb has developed to facilitate prehension, i.e. the placing of the hand in three-dimensional space. However, mobility of the hand on the forearm has evolved at the expense of stability. A wrist is said to be kinetically unstable when it cannot bear physiological loads without giving way or causing injury. A wrist is kinematically unstable when it exhibits sudden changes in carpal alignment, i.e. during a specific movement there is a ‘clunk’ as one or more of the carpal bones moves abnormally with respect to the others. Stability of the various joints such that the bones maintain normal anatomical relations with respect to each other throughout the normal range of motion is essential for physiological load-bearing.

Some degree of carpal instability may occur as part of inherent hypermobility in affected individuals, but usually it occurs only after rupture or attenuation of intrinsic and extrinsic carpal ligaments and may be detected either clinically or evidenced on radiographs as malalignment of the carpal bones (Fig. 50.22).
Fig. 50.22 Scapholunate dissociation shown in posteroanterior power grip view (A) and lateral view (B). Dissociation between the scaphoid and lunate as shown here leads to collapse of the scaphoid into flexion and the lunate into extension (dorsal intercalated segment instability, or DISI) thus removing the inbuilt tension across the proximal row. This causes the gap (so called Terry Thomas sign) between the scaphoid and lunate in the PA radiograph (marked with asterisk) and increased scapholunate angle above the upper limit of normal of 60 degrees, as shown in B.
CARPOMETACARPAL JOINTS

The first carpometacarpal joint, CMCJ, or basal joint of the thumb, is a modified saddle joint that permits opposition of the thumb and confers the ability to hold and manipulate objects: the actions of ‘pinch’ grip, ‘tripod' pinch and ‘chuck' grip are specifically facilitated. Significant forces pass across and compress this joint compared to the remaining CMCJs. The second to fifth CMCJs exhibit an increasing range of movement progressing from the radial to the ulnar side. Thus there is little mobility at the base of the index ray, but considerable mobility at the base of the small finger ray, which facilitates ‘cupping' of the palm of the hand. Compressive forces between the metacarpals and the distal carpal row are estimated to be upwards of ten times the forces at the tips of the fingers during ‘pinch' or ‘chuck' grip.

Carpometacarpal joint of the thumb

Articulating surfaces

The carpometacarpal joint of the thumb is a sellar (saddle) joint between the first metacarpal base and trapezium. It enjoys wide mobility due to its extensive articular surfaces and their topology.

Ligaments

The first metacarpal and trapezium are connected by lateral, anterior and posterior ligaments and a fibrous capsule. The broad lateral ligament runs from the lateral surface of the trapezium to the radial side of the metacarpal base. The palmar and dorsal ligaments are oblique bands which converge to the ulnar side of the metacarpal base from the palmar and dorsal surfaces of the trapezium respectively.

Synovial membrane

The synovial membrane lines the joint capsule and is separate from it.

Vascular supply

The carpometacarpal joint of the thumb receives its blood supply from the radial artery and its first dorsal metacarpal branch.

Innervation

The carpometacarpal joint of the thumb is innervated by articular twigs from the posterior interosseous nerve and the superficial branch of the radial nerve.

Joint movements
Except at initiation, flexion is accompanied by medial rotation; conversely, medial rotation involves flexion. Linkage of movements is due largely to the shape of the articular surfaces (which impose some conjunct rotation), and to the obliquity of the dorsal ligament (which, when taut, anchors the ulnar side of the metacarpal base while its radial side continues to move). Contraction of flexor pollicis brevis, assisted by opponens pollicis, thus produces medial rotation with flexion; combined with abduction this brings the thumb pulp into contact with the pulps of the slightly flexed fingers, a movement termed opposition. (The flexed fingers have varying degrees of lateral metacarpophalangeal rotation, which is minimal in the index, and maximal in the minimus.) Conversely, full extension of the thumb metacarpal entails slight lateral rotation, attributable to the sellar form of the joint and to the action of the palmar ligament (which is similar to that of the dorsal ligament in flexion). (See also p. 888.)

**Muscles producing movements**

The muscles producing movements at the carpometacarpal joint of the thumb are as follows.

**Flexion**

Flexor pollicis brevis and opponens pollicis, aided by flexor pollicis longus when the other joints of the thumb are flexed. Flexion entails medial rotation.

**Extension**

Abductor pollicis longus and extensors pollicis brevis and longus. In full extension extensor pollicis longus, owing to its oblique pull and the disposition of the palmar ligament, rotates the thumb laterally and draws it dorsally, i.e. slightly adducts the thumb.

**Abduction**

Abductors pollicis brevis and longus. When abduction is maximal the digit and metacarpal are not in line, and the thumb is abducted at both metacarpophalangeal and carpometacarpal joints.

**Adduction**

Adductor pollicis alone.

**Opposition**

Opponens pollicis and flexor brevis pollicis simultaneously flex and medially rotate the abducted thumb. Interpulpal pressure, or that generated by digital grasping, is increased by adductor pollicis and flexor pollicis longus.
Circumduction

Extensors, abductors, flexors and adductors acting consecutively in this, or reverse, order.

**Second to fifth carpometacarpal joints**

The second to fifth carpometacarpal joints are synovial ellipsoid joints between the carpus and second to fifth metacarpals. Although widely classed as plane, they have curved articular surfaces which are often of complex sellar shape. The bones are united by articular capsules, and dorsal, palmar and interosseous ligaments.

**Ligaments**

The dorsal ligaments are the strongest, and connect the dorsal surfaces of the carpal and metacarpal bones. The second metacarpal has two ligaments, from the trapezium and trapezoid; the third has two, from the trapezoid and capitate; the fourth has two, from the capitate and hamate; the fifth has a single band from the hamate, which is continuous with a similar palmar ligament, forming an incomplete capsule.

The palmar ligaments are similar, except that the third metacarpal has three: a lateral from the trapezium, superficial to the tendon sheath of flexor carpi radialis, an intermediate from the capitate, and a medial from the hamate.

The interosseous ligaments consist of two short, thick, fibrous bands. They are limited to one part of the carpometacarpal articulation and connect contiguous distal margins of the capitate and hamate with adjacent surfaces of the third and fourth metacarpal bones: they may be united proximally.

**Synovial membranes**

The synovial membranes are often continuous with those of the intercarpal joints. Occasionally, the joint between the hamate and fourth and fifth metacarpal bones has a separate synovial cavity, bounded laterally by the medial interosseous ligament and its extensions to the palmar and dorsal parts of the capsule.

**Vascular supply**

The second to fifth carpometacarpal joints are supplied by the posterior carpal branches of the radial and ulnar arteries, by twigs from the anterior interosseous artery, and from the palmar digital arteries.

**Innervation**

The second to fifth carpometacarpal joints are innervated by the deep
terminal branches of the ulnar nerve, the anterior interosseous branch of the median nerve, and the short branches of the superficial radial and dorsal ulnar nerves.

Muscles producing movements

Slight gliding movements are effected by the long flexor and extensor muscles of the digits.
INTERMETACARPAL JOINTS

Articulating surfaces

The second to fifth metacarpal bases articulate reciprocally by small cartilage-covered facets connected by dorsal, palmar and interosseous ligaments.

Fibrous capsule

The intermetacarpal joints have fibrous capsules.

Ligaments

The dorsal and palmar ligaments pass transversely from bone to bone. The interosseous ligaments connect contiguous surfaces just distal to their articular facets.

Synovial membranes

The synovial membranes are continuous with those of the carpometacarpal articulations.

Movements at the carpometacarpal and intermetacarpal joints

Movements at the carpometacarpal and intermetacarpal articulations are limited to slight gliding, sufficient to permit some flexion–extension and adjunct rotation: ranges vary in different joints. They are partly accessory movements occurring when the palm is ‘cupped’, as in grasping an object. Active movements also occur and are familiar, e.g. to the pianist or violinist. The fifth metacarpal is most movable and the second and third are the least mobile. These variations are easily demonstrated by opposing each digit to the thumb over the palmar centre. About two-thirds of the movements are pollicial, as described above, but during opposition to minimus, the latter is flexed, abducted and laterally rotated, accounting for the remaining third of the movement. These actions occur at both the carpometacarpal and metacarpophalangeal joints. The close-packed position probably coincides with carpal extension, as in gripping. Further accessory movements are spiral twisting of the whole metacarpus on the carpus.

Muscles producing movements

Movements at carpometacarpal and intermetacarpal joints are effected by the flexors and extensors of the second to fifth digits.
METACARPOPHALANGEAL JOINTS

The metacarpophalangeal joints are usually considered ellipsoid. However, the metacarpal heads are adapted to shallow concavities on the phalangeal bases: they are not regularly convex but partially divided on their palmar aspects and thus almost bicondylar (Fig. 50.23).

Fig. 50.23 Metacarpophalangeal and digital joints of the left third finger: medial aspect.

Fibrous capsule

The metacarpophalangeal joints all have fibrous capsules.

Ligaments
Each metacarpophalangeal joint has a palmar and two collateral ligaments.

**Palmar ligaments**

The palmar (volar plates) ligaments are unusual. They are thick, dense and fibrocartilaginous, and sited between, and connected to, the collateral ligaments. They are attached loosely to the metacarpals but firmly to the phalangeal bases. Their palmar aspects are blended with the deep transverse palmar ligaments and are grooved for the flexor tendons, whose fibrous sheaths connect with the sides of the grooves. Their deep surfaces increase articular areas for the metacarpal heads.

**Deep transverse metacarpal ligaments**

The deep transverse metacarpal ligaments are three short, wide, flat bands which connect the palmar ligaments of the second to fifth metacarpophalangeal joints. They are related anteriorly to the lumbricals and digital vessels and nerves, and posteriorly to the interossei. Bands from the digital slips of the central palmar aponeurosis join their palmar surfaces. On both sides of the third and fourth metacarpophalangeal joints, but only the ulnar side of the second and radial side of the fifth, transverse bands of the dorsal digital expansions join the deep transverse metacarpal ligaments. The lumbricals and the phalangeal attachments of the dorsal interossei lie anterior to this band, and the remaining attachments of dorsal interossei and palmar interossei are posterior to it (see Fig. 50.30).

**Collateral ligaments**

The collateral ligaments are strong, round cords which flank the joints. Each is attached to the posterior tubercle and adjacent pit on the side of its metacarpal head, and each passes distoanteriorly to the side of the anterior aspect of its phalangeal base (Fig. 50.23).

**Synovial membrane**

The metacarpophalangeal joints are lined by a synovial membrane.

**Vascular supply**

The metacarpophalangeal joints receive their blood supply from the dorsal and palmar metacarpal arteries, the arteria princeps pollicis, and the arteria radialis indicis.

**Innervation**

The metacarpophalangeal joints are innervated by twigs from the palmar digital branches of the median nerve, the deep terminal branch of the ulnar nerve, and the posterior interosseous nerve.

**Joint movements**

Flexion, extension, adduction, abduction, circumduction and limited rotation all take place at the metacarpophalangeal joints. Rotation cannot occur in isolation, but may accompany flexion–extension. This may be initiated voluntarily in the free hand (e.g. each finger flexing and rotating to place its tip near the palmar centre); the range of rotation is frequently increased as a result of the resistance of a grasped object.
Flexion is almost 90°, whereas extension is only a few degrees: both movements are limited mostly by antagonistic muscles. Flexion is often terminated by the resistance offered by a grasped object. The metacarpophalangeal joint of the thumb has a flexion–extension range of approximately 60°, which is almost entirely flexion. Slight lateral rotation accompanies digital flexion of digits 3–5. Flexion of the index finger may be accompanied by minimal lateral rotation or no rotation: a small degree of medial rotation is frequently observed. Other movements are adduction–abduction (maximal range 25°), which invariably accompanies the corresponding carpometacarpal movements and increases their combined range, and slight conjunct rotation, but greater adjunct rotation, which accompanies flexion–extension. Of the second to fifth metacarpophalangeal joints, the second is most mobile in adduction–abduction (approximately 30°), followed by the fifth, fourth, and third.

Accessory movements

Accessory movements are further rotation (most marked in the thumb), anteroposterior and lateral translation of a phalanx or metacarpal, and distraction.

Muscles producing movements

The muscles producing movements at the metacarpophalangeal joints are as follows.

Flexion

Flexores digitorum superficialis and profundus, assisted by the lumbricals and interossei and, in the minimus, flexor digiti minimi brevis. In the thumb, flexores pollicis longus and brevis and the first palmar interosseous.

Extension

Extensor digitorum, assisted in the second and fifth digits by extensor indicis and extensor digiti minimi respectively. In the thumb, extensors pollicis longus and brevis.

Adduction

In extended fingers, palmar interossei; the long flexors are predominant during flexion. In the thumb, limited metacarpophalangeal adduction is possible and may be attributable to adductor pollicis and the first palmar interosseous.

Abduction

In extended fingers, dorsal interossei assisted by the long extensors (except in the middle finger), and abductor digitii minimi in the little finger. In the thumb, abductor pollicis brevis (which also contributes to opposition). When the fingers are flexed at the IP joints, active abduction is impossible: if the long digital flexors are inactive, passive abduction is free. Inability to abduct actively in this position may be due to shortening of the dorsal interossei and abductor digiti minimi by flexion. However the altered line of pull of the interossei relative to the axis of movement is probably the determining factor: in digital extension the axis of lateral movements is anteroposterior, whereas in flexion it is proximodistal, and the line of pull of the interossei is then nearly parallel to the axis.

Gamekeeper's thumb
The ulnar collateral ligament of the metacarpophalangeal joint of the thumb can be avulsed from its distal attachment to the base of the proximal phalanx by a combination of forced extension and radial deviation of the joint. The injury was reported to occur in gamekeepers while breaking the necks of game, but can occur following simple falls onto the outstretched hand, especially in skiers who have the straps of ski poles wrapped around their thumbs.

The ulnar collateral ligament is normally covered by the aponeurotic insertion of the adductor pollicis tendon. Following avulsion, the proximal end can become superficially displaced around the proximal free edge of the aponeurotic insertion of the adductor. This soft tissue interposition prevents the ends of the avulsed ligament from healing. If left untreated, a firm palpable inflammatory swelling occurs, known as the ‘Stener lesion’. Surgical repair requires division of the aponeurotic insertion of adductor pollicis, followed by bony reattachment of the avulsed ligament and repair of the aponeurosis.
INTERPHALANGEAL JOINTS

The interphalangeal joints are uniaxial hinge joints (Fig. 50.23).

Fibrous capsule

Each interphalangeal joint has a fibrous capsule.

Ligaments

Each interphalangeal joint has a palmar ligament (also known as the volar plate) and two collateral ligaments. The long extensor tendons take the place of the dorsal capsular ligaments. Extensions from the extensor expansion, each collateral ligament and the palmar ligament, all pass into the joint cavity and provide a significant increase to the articular surface area of the phalangeal base: their deformable nature improves joint congruence.

Palmar ligament (volar plate)

The volar plate constitutes the floor of the interphalangeal joint. In the proximal interphalangeal joint, the distal end of the volar plate is thickened laterally where it is firmly attached to the base of the middle phalanx at the position of the true collateral ligament attachment. Centrally, it is more delicate and blends with the volar periosteum of the middle phalanx. Proximally, the volar plate is also very delicate in its central portion, but it is thickened laterally to form the so-called check rein ligaments which attach to the periosteum of the proximal phalanx just within the walls of the A2 pulley component of the fibrous flexor sheath. Nutrient branches of the digital arteries pass underneath these check ligaments to reach the vinculae (Fig. 50.24). A detailed account of the anatomy of the volar plate can be found in Bowers et al (1980).
Fig. 50.24 Anatomy of the proximal interphalangeal joint volar plate. The blood vessel supplying the flexor tendons via the vincula brevum is shown, but the mesentery forming the vinculum has been omitted.

**Collateral ligaments**

The collateral ligaments pass from the lateral aspect of the head of one phalanx to the volar aspect of the base of the adjacent phalanx. An accessory component to the collateral ligament arises in continuity with the main ligament and passes in a volar direction to attach to the volar plate.
Synovial membrane

Each interphalangeal joint has a synovial lining.

Vascular supply

The interphalangeal joints are supplied by branches from the palmar digital arteries.

Innervation

The interphalangeal joints are innervated by the palmar digital branches of the median nerve (to the thumb, index, middle and ring fingers), and the ulnar nerve (to the ring and little fingers).

Factors maintaining stability

Stability is conferred by the articular contours of the joint surfaces and the collateral ligaments. The flexor and extensor tendons and retinacular ligaments provide secondary stabilization. Stability against hyperextension of the proximal interphalangeal joint is enhanced by the three-dimensional box arrangement that is produced by the collateral ligament–volar plate complex.

Joint movements

Movements (active) at the interphalangeal joints are flexion and extension, and are greater in range at the proximal joints. Flexion is considerable, whereas extension is limited by tension of the digital flexors and terminated by tension in the palmar ligaments and nonarticular compression. Full extension is the close-packed position, which is assumed whenever the fingers are used as props to transmit body weight or powerful thrust. In contrast, the fully clenched fist may also be used for this purpose. Flexion and extension are accompanied by slight conjunct rotation: during flexion this turns the digital pulps slightly laterally, i.e. to face the opposed thumb, and an opposite rotation occurs during extension.

Accessory movements

Accessory movements are limited rotation, abduction, adduction and anteroposterior translation. They permit the fingers to adapt to the shapes of gripped objects and help to protect against stresses and strains.

Muscles producing movements

The muscles producing movements at the interphalangeal joints are as follows.

Flexion
At proximal interphalangeal joints, flexores digitorum superficialis and profundus; at distal interphalangeal joints, flexor digitorum profundus; at the thumb interphalangeal joint, flexor pollicis longus.

Extension

Extensores digitorum, digiti minimi and pollicis longus, in association with abductor pollicis longus and extensor pollicis brevis. Extension occurs simultaneously in both joints in digits 2–5.

Simultaneous flexion at the metacarpophalangeal joints and extension at the interphalangeal joints of a digit are essential for the fine movements of writing, drawing, threading a needle, etc. The lumbricals and interossei have long been accepted as not only primary agents in flexing the metacarpophalangeal joints but also in extending the interphalangeal joints via their attachments to the dorsal digital expansions.

Mallet finger

Mallet finger is a traumatic rupture, avulsion fracture or laceration of the terminal slip of the extensor tendon to the terminal phalanx of the finger. It can result from forced flexion of the distal phalanx of the fully extended finger and is a well-known injury in cricketers. The patient is unable actively to extend the terminal phalanx although the distal interphalangeal joint can be extended passively.

Swan neck deformity

Swan neck deformity involves hyperextension of the proximal interphalangeal joint together with distal interphalangeal joint flexion. It is caused by a relative overactivity of the extensors acting at the proximal interphalangeal joint compared with the flexors. It arises as a result of intrinsic muscle spasm, long standing mallet finger or dysfunction of flexor digitorum superficialis and can only occur if there is also some laxity of the volar plate.

Boutonnière deformity

Boutonnière deformity is a flexion deformity of the proximal interphalangeal joint following either division or laxity in the central slip of the extensor tendon, which normally inserts into the base of the middle phalanx. An essential feature is hyperextension at the distal interphalangeal joint. It usually occurs as a result of either trauma or rheumatoid arthritis which cause the lateral bands of the extensor tendon to migrate in a volar direction and the head of the proximal phalanx to migrate dorsally. Initially the deformity is passively correctable. With time, the soft tissues around the joint contract and a fixed deformity results.
MUSCLE

EXTRINSIC LONG FLEXORS AND EXTensors

The extrinsic long flexors and extensors are described on page 845.

Flexor retinaculum

The flexor retinaculum is a strong, fibrous band (Fig. 50.25). It crosses the front of the carpus and converts its anterior concavity into the carpal tunnel which transmits the flexor tendons of the digits and the median nerve. The retinaculum is short and broad, measuring 2.5–3 cm both transversely and proximodistally. It is attached medially to the pisiform and the hook of the hamate. Laterally, it splits into superficial and deep laminae. The superficial lamina is attached to the tubercles of the scaphoid and trapezium. The deep lamina is attached to the medial lip of the groove on the trapezium. Together with this groove, the two laminae form a tunnel, lined by a synovial sheath, which contains the tendon of flexor carpi radialis. The retinaculum is crossed superficially by the ulnar vessels and nerve – immediately radial to the pisiform – and by the palmar cutaneous branches of the median and ulnar nerves. A slender band of fascia, the superficial part of the flexor retinaculum, bridges over the ulnar neurovascular bundle and attaches to the radial side of the pisiform, forming a tunnel (Guyon's canal) which is an occasional site of ulnar nerve entrapment. The tendons of palmaris longus and flexor carpi ulnaris are partly attached to the anterior surface of the retinaculum. Distally some of the intrinsic muscles of the thumb and little finger are attached to the retinaculum.

Fig. 50.25 Transverse section through the left wrist at the level of the carpus, showing the muscle tendons and their synovial sheaths.

Long flexor tendon apparatus

Flexor tendon sheaths

The fibrous sheaths of the flexor tendons are specialized parts of the palmar fascial continuum. Each finger has an osseoaponeurotic tunnel which extends from midpalm
to the distal phalanx. The thumb has a tunnel for flexor pollicis longus which extends from the metacarpal to the distal phalanx. The proximal border is to some extent a matter of definition, because the transverse fibres of the palmar aponeurosis may be considered to be a part of the pulley system. The sheath consists of arcuate fibres which arch anteriorly over bone, tendons (where the sheath is required to be stiff), and the centres of joints (where a bucket-handle of arcuate fibres is a mechanically favourable arrangement). In contrast, where the sheath is required to fold to permit joint flexion, it consists of cruciate fibres. These fibrous sheaths are lined by a thin synovial membrane which provides a sealed lubrication system containing synovial fluid. The synovial membrane extends from the distal phalanx to midpalm in the case of the index, middle and ring fingers, and further proximally in the case of the little finger (Fig. 50.26). The sheaths around the thumb and little finger are continuous with the flexor sheaths in front of the wrist. The parietal synovial membrane is reflected onto the surface of the flexor tendon, forming a visceral synovium.

Fig. 50.26 Synovial sheaths of the tendons and flexor tendon sheaths on the flexor aspect of the left wrist and hand.
A standard nomenclature for the anular and cruciform pulleys that make up the sheath has been adopted by the American Society for Surgery of the Hand: the letters A and C respectively are used (Doyle & Blythe 1975).

The usual pattern is as follows (Fig. 50.26). The A1 pulley is situated anterior to the palmar cartilaginous plate of the metacarpophalangeal joint and may extend over the proximal part of the proximal phalanx. The A2 overlies the middle third of the proximal phalanx. It is the strongest pulley and arises from well-defined longitudinal ridges on the palmar aspect of the phalanx. Its distal edge is well developed. A pouch or recess of synovium extends superficial to the free edge of the pulley fibres so that the free edge forms a lip protruding into the synovial space. A3 is a narrow pulley lying palmar to the proximal interphalangeal joint. A4 overlies the middle third of the middle phalanx, and A5 overlies the distal interphalangeal joint. The cruciate fibres are numbered in a slightly different manner. C0 is palmar to the metacarpophalangeal joint. There are two cruciate zones, C1 and C2, at the proximal interphalangeal joint and they lie just proximal and distal respectively to A3. At the distal interphalangeal joint there is one pronounced cruciate system, C3, which lies between A4 and A5. Variations occur frequently. During flexion, the cruciate fibres become orientated more transversely in the digits and the edges of adjacent anular pulleys approximate so that they form, in full flexion, a continuous tunnel of transversely orientated fibres. Surgically the most important pulleys which prevent bowstringing of the flexor tendons are the A2 and A4 pulleys.

The pulley arrangement in the thumb is different from that in the other digits. There are three constant pulleys — two anular and one oblique (Fig. 50.27). The A1 pulley is located at the metacarpophalangeal joint. The oblique pulley is located over the mid-portion of the proximal phalanx, and its fibres pass from the ulnar aspect proximally to the radial aspect dorsally. The A2 pulley is thinner than the A1 pulley and is situated just proximal to the interphalangeal joint. The oblique pulley is the most important pulley in the thumb for maintaining the action of flexor pollicis longus.
Synovial sheaths of the carpal flexor tendons

Two synovial sheaths envelop the flexor tendons as they traverse the carpal tunnel, one for the flexores digitorum superficialis and profundus, the other for flexor pollicis longus (Fig. 50.25). These sheaths typically extend into the forearm for 2.5 cm proximal to the flexor retinaculum, and occasionally communicate with each other deep to it. The sheath of the flexores digitorum tendons reaches about halfway along the metacarpal bones, where it ends in blind diverticula around the tendons to the index, middle and ring fingers (Fig. 50.26). The sheath is prolonged around the tendons to the little finger and is usually continuous with their digital synovial sheath. A transverse section through the carpus shows that the tendons are invaginated into the sheath from the lateral side (Fig. 50.25). The parietal layer lines the flexor retinaculum and the floor of the carpal tunnel. It is reflected laterally as the visceral layer over the tendons of flexor digitorum superficialis ventrally and flexor digitorum profundus dorsally. Medially a recess formed by the visceral layer of the sheath insinuates between the two groups of tendons and passes laterally for a variable distance. The sheath of flexor pollicis longus, which is usually separate, is continued along the thumb as far as the insertion of the tendon.

Vincula

The phenomenon of tendon gliding within a fibrous sheath requires a very specialized arrangement of the vascular supply. Folds of synovial membrane containing a loose
plexus of fascial fibres carry blood vessels to the tendons at certain defined points (Fig. 50.28). These folds, vincula tendinum, are of two kinds. Vincula brevia, of which there are two in each finger, are attached to the deep surfaces of the tendons near to their insertions. There is thus one vinculum brevium attaching flexor digitorum profundus to the region of the distal interphalangeal joint, and a more proximal vinculum deep to flexor digitorum superficialis at the proximal interphalangeal joint. Vincula longa are filiform: usually two are attached to each superficial tendon, one to each deep tendon.

**Fig. 50.28** Lateral part of the left hand showing the tendons and vincula tendinum of the index finger and the muscles in the first intermetacarpal space.

**Trigger finger**

Trigger finger is a stenosing tenovaginitis which affects the fibrous flexor sheaths of the fingers or thumb within the palm. The affected sheath thickens and entraps the contained tendons, which become constricted at the site of entrapment and bulge distal to it, to produce a distinct nodule in the palm of the hand. The finger now snaps as the tendon nodule passes through the constriction on flexing the finger. The corresponding extensor muscle is insufficiently powerful to extend the affected finger. The patient does this passively, accompanied by a painful snap. Treatment frequently requires surgical division of the A1 pulley of the flexor sheath to relieve the stricture.

**Extensor retinaculum**

The extensor retinaculum is a strong, fibrous band which extends obliquely across the back of the wrist (Fig. 50.29). It is attached laterally to the anterior border of the
radius, medially to the triquetral and pisiform bones, and, in passing across the wrist, to the ridges on the dorsal aspect of the distal end of the radius. It prevents bowstringing of the tendons across the wrist joint.
Synovial sheaths of the carpal extensor tendons

Six tunnels deep to the extensor retinaculum transmit the extensor tendons, each contains a synovial sheath. The tendons of abductor pollicis longus and extensor pollicis brevis lie in a tunnel on the lateral side of the styloid process of the radius. Occasionally there may be a separate synovial sheath for each, or the tendon of the abductor may be double. The tendons of extensores carpi radiales longus and brevis lie behind the styloid process. The tendon of extensor pollicis longus lies on the medial side of the dorsal tubercle of the radius and the tendons of extensor digitorum and extensor indicis lie in a tunnel on the medial side of the tubercle. The tendon of extensor digiti minimi lies opposite the interval between the radius and ulna, and the tendon of extensor carpi ulnaris lies between the head and the styloid process of the ulna.

The tendon sheaths of abductor pollicis longus, extensores pollicis brevis and longus, extensores carpi radiales and extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones; those of extensor digitorum, extensor indicis and extensor digiti minimi are sometimes prolonged a little more distally along the metacarpus.

De Quervain's tenovaginitis

De Quervain's tenovaginitis is a stenosing tenovaginitis of unknown aetiology which occurs in the first dorsal compartment at the level of the radial styloid. It involves the common extensor sheath containing the tendons of abductor pollicis longus and extensor pollicis brevis. There is palpable thickening of the tendon sheath with painful limitation of extension of the thumb. Treatment frequently requires division of the thickened sheath, care being taken to avoid the adjacent superficial radial nerve. Division of the sheath produces no functional impairment.

Extensor tendon apparatus
The extensor digitorum tendons emerge through the fourth dorsal compartment onto the dorsum of the hand, where they are joined together distally by a varying pattern of oblique interconnections, the juncturae tendinae. These typically pass in a distal direction from middle finger to index finger and from ring finger to middle and little fingers. Proximal lacerations to the middle finger extensor tendon may result in only partial loss of extension because of these tendinous interconnections.

At the level of the metacarpophalangeal joint, each extensor tendon is held in a central position over the dorsum of the joint by a flat fibrous extensor expansion (Fig. 50.30). The expansion extends onto the dorsum of the proximal phalanx of each digit. It forms a movable hood, which moves distally when the metacarpophalangeal joint is flexed, and proximally when it is extended (in which position it is most closely applied to the joint).

Each extensor tendon blends with the extensor expansion along its central axis, and is separated from the metacarpophalangeal joint by a small bursa. The expansion is triangular in shape, with its base proximal. It receives the conjoined tendons of the intrinsic muscles. The expansion is almost translucent between its margins and the extensor digitorum tendon. Transverse fibres (the sagittal bands) pass to the volar plate and transverse metacarpal ligaments. They separate the phalangeal attachment of the dorsal interosseus from the rest of the muscle, and the palmar interosseus from the lumbrical muscle. Injuries to the sagittal bands can lead to subluxation of the extensor tendon.

The margins of the extensor expansions are thickened on the radial side by the tendons of lumbrical and interosseous muscles and on the ulnar side by the tendon of an interosseous alone or, in the case of the fifth digit, by abductor digiti minimi.

The interossei tendons join the extensor expansion at the level of the proximal portion of the proximal phalanx, while the lumbrical tendons join the extensor mechanism further distally at the mid-portion of the proximal phalanx. Their line of pull is proximal to the axis of rotation at the metacarpophalangeal joint, but dorsal to the axis of rotation at the proximal interphalangeal joint. The extensor mechanism trifurcates into a central slip and two lateral bands just proximal to the proximal interphalangeal joint. The central slip receives a contribution from the lumbrical and interosseous tendons via the lateral bands. Similarly, some fibres from the central region pass to each lateral band, producing a criss-cross arrangement of fibres. The central slip attaches to the base of the middle phalanx, while the lateral bands continue distally and eventually fuse together and insert into the distal phalanx. The tension in the central slip and the lateral bands varies as the finger moves between flexion and extension and plays a crucial role in coordinating synchronous activity between the proximal and distal interphalangeal joints.

The transverse and oblique retinacular ligaments of Landsmeer connect the fibrous flexor sheath to the extensor apparatus. The transverse retinacular ligament passes from the A3 pulley of the fibrous flexor sheath at the level of the proximal interphalangeal joint to the lateral border of the lateral extensor band. The oblique retinacular ligament lies deep to the transverse retinacular ligament. It originates from the lateral aspect of the proximal phalanx and flexor sheath (A2 pulley) and passes volar to the axis of rotation of the proximal interphalangeal joint but in a dorsal and distal direction to insert into the terminal extensor tendon.
The intrinsic muscles of the hand are organized into three groups plus a superficial muscle. Flexor pollicis brevis, abductor pollicis brevis, opponens pollicis and adductor pollicis all act on the thumb and are known collectively as the thenar muscles. Abductor digiti minimi, flexor digiti minimi brevis and opponens digiti minimi all act on the little finger and are known collectively as hypothenar muscles. Interossei and lumbricals act on the fingers. Palmaris brevis is a superficial muscle that lies beneath the ulnar palmar skin.

**Flexor pollicis brevis**

**Attachments**

Flexor pollicis brevis lies medial to abductor pollicis brevis (Fig. 50.31). It has superficial and deep parts. The superficial head arises from the distal border of the flexor retinaculum and the distal part of the tubercle of the trapezium, and passes along the radial side of the tendon of flexor pollicis longus. It is attached, by a tendon that contains a sesamoid bone, to the radial side of the base of the proximal phalanx of the thumb. The deep part arises from the trapezoid and capitate bones and from the palmar ligaments of the distal row of carpal bones, and passes deep to the tendon of flexor pollicis longus. It unites with the superficial head on the sesamoid bone and base of the first phalanx.
The superficial head is frequently blended with opponens pollicis. The deep head varies considerably in size and may even be absent.

**Relations**

Flexor pollicis brevis lies superficial in the thenar eminence and is distal to abductor pollicis brevis. It is crossed by the motor branch of the median nerve.

**Vascular supply**

Flexor pollicis brevis is supplied by the superficial palmar branch of the radial artery, and branches from the princeps pollicis artery and radialis indicis artery.

**Innervation**

The superficial head of flexor pollicis brevis is usually innervated by the lateral terminal branch (motor branch) of the median nerve. The deep head is usually innervated by the deep branch of the ulnar nerve, C8 and T1. Some variation is common.
Action

Flexor pollicis brevis flexes the metacarpophalangeal joint.

Testing

Flexor pollicis brevis is palpated in the thenar eminence while the subject flexes the metacarpophalangeal joint of the thumb, keeping the interphalangeal joint fully extended.

Abductor pollicis brevis

Attachments

Abductor pollicis brevis is a thin, subcutaneous muscle in the proximolateral part of the thenar eminence (Fig. 50.31). It arises mainly from the flexor retinaculum, but a few fibres spring from the tubercles of the scaphoid bone and trapezium, and from the tendon of abductor pollicis longus. Its medial fibres are attached by a thin, flat tendon to the radial side of the base of the proximal phalanx of the thumb, and its lateral fibres join the dorsal digital expansion of the thumb. The muscle may receive accessory slips from the long and short extensors of the thumb, opponens pollicis, or the styloid process of the radius.

Relations

Abductor pollicis brevis lies proximomedial to flexor pollicis brevis in the superficial part of the thenar eminence.

Vascular supply

Abductor pollicis brevis is supplied by the superficial palmar branch of the radial artery, and often by an independent branch directly from the radial artery lying on the radial aspect of thumb.

Innervation

Abductor pollicis brevis is innervated by the lateral terminal branch (motor branch) of the median nerve, C8 and T1. Note that this is the only muscle of the thenar eminence which is constantly supplied by the median nerve.

Action

Abductor pollicis brevis draws the thumb ventrally in a plane at right angles to the palm of the hand (abduction).

Testing

The hand is placed with its dorsum on the table. The subject's thumb is placed so that the nail is in a plane at right angles to the palm of the hand. The subject is instructed to touch with his thumb an object held vertically above the thumb. This is a highly specific test for a median nerve lesion.

Opponens pollicis
Attachments

Opponens pollicis lies deep to abductor pollicis brevis (Fig. 50.31). It arises from the tubercle of the trapezium and the flexor retinaculum, and is attached to the whole length of the lateral border, and the adjoining lateral half of the palmar surface of the metacarpal bone of the thumb.

Relations

Opponens pollicis lies deep between the other two muscles of the thenar eminence and is only revealed when they are retracted.

Vascular supply

Opponens pollicis is supplied by the superficial palmar branch of the radial artery, and by branches from the first palmar metacarpal artery (when present), princeps pollicis artery, radialis indicis artery and the deep palmar arch.

Innervation

Opponens pollicis is innervated by the lateral terminal branch of the median nerve, C8 and T1, and commonly by a branch of the deep terminal branch of the ulnar nerve.

Action

Opponens pollicis flexes the metacarpal bone of the thumb.

Testing

The subject tries, against resistance, to touch the tip of the little finger with the thumb. The key observation is whether or not the thumb can be strongly adducted without flexing the IP joint.

Adductor pollicis

Attachments

Adductor pollicis arises by oblique and transverse heads (Fig. 50.31). The oblique head is attached to the capitate bone, the bases of the second and third metacarpal bones, the palmar ligaments of the carpus and the sheath of the tendon of flexor carpi radialis. Most of the fibres converge into a tendon (which contains a sesamoid bone), which unites with the tendon of the transverse head, and is attached to the ulnar side of the base of the proximal phalanx of the thumb. The deepest fibres may pass into the medial side of the dorsal digital expansion of the thumb. On the lateral side of the oblique head a considerable fasciculus passes deep to the tendon of flexor pollicis longus to join flexor pollicis brevis; this has been described as the 'deep head' of flexor pollicis brevis. The transverse head is the deepest of the pollicial muscles, it is triangular, and arises from the distal two-thirds of the palmar surface of the third metacarpal. The fibres converge to be attached, with the oblique head and the first palmar interosseous, to the base of the proximal phalanx of the thumb. The two parts of the adductor vary in relative size and degree of connection.

Relations
The deep palmar arch and the deep branch of the ulnar nerve pass between the two heads of the muscle. Anteriorly adductor pollicis is crossed by the flexor tendons of the index finger and their sheath, and the first lumbrical, and is overlapped by flexor pollicis brevis. Posteriorly it abuts against the first dorsal interosseous muscle: together these muscles form the mass of the first web space of the hand.

Vascular supply
Adductor pollicis is supplied by the arteria princeps pollicis and the arteria radialis indicis (which are sometimes combined as the first palmar metacarpal artery) and by branches from the deep palmar arch.

Innervation
Adductor pollicis is innervated by the deep branch of the ulnar nerve, C8 and T1.

Action
Adductor pollicis approximates the thumb to the palm of the hand. It acts to greatest advantage when the abducted, rotated and flexed thumb is opposed to the fingers in gripping.

Testing
With the thumb lying along the palmar aspect of the index finger, and with its nail in a plane at right angles to the palm, the subject is asked to retain a strip of paper between the thumb and palm against resistance.

Abductor digiti minimi
Attachments
Abductor digiti minimi arises from the pisiform bone, the tendon of flexor carpi ulnaris and the pisohamate ligament (Fig. 50.31). It ends in a flat tendon which divides into two slips: one is attached to the ulnar side of the base of the proximal phalanx of the little finger, and the other to the ulnar border of the dorsal digital expansion of extensor digiti minimi.

The muscle may have two or three slips and may be fused with flexor digiti minimi brevis. An additional slip may arise from flexor retinaculum, antebrachial fascia, or tendons of palmaris longus or flexor carpi ulnaris. It may be partly attached to the fifth metacarpal by a slip from the pisiform.

Relations
Abductor digiti minimi lies along the ulnar border of flexor digiti minimi brevis and overlies opponens digitii minimi.

Vascular supply
Abductor digiti minimi is supplied by the deep palmar branch of the ulnar artery, branches from the ulnar end of the superficial palmar arch and the palmar digital artery for the medial border of the little finger.
Innervation

Abductor digiti minimi is innervated by the deep branch of the ulnar nerve, C8 and T1.

Action

Abductor digiti minimi abducts the little finger away from the fourth, e.g. in the habitual spreading of the digits when they are extended. Abduction is also possible when digits 2–4 are tightly adducted in flexion or extension.

Testing

Abductor digiti minimi is tested by abducting the little finger against resistance.

Flexor digiti minimi brevis

Attachments

Flexor digiti minimi brevis arises from the convex surface of the hook of the hamate and the palmar surface of the flexor retinaculum. It inserts into the ulnar side of the base of the proximal phalanx of the little finger with abductor digiti minimi.

It may be absent, or fused with the abductor, and it may attach to the distal end of the fifth metacarpal by a muscular slip.

Relations

Flexor digiti minimi brevis lies lateral to the abductor. Its origin is separated from that of the abductor by the deep branches of the ulnar artery and nerve.

Vascular supply

Flexor digiti minimi brevis is supplied by the deep palmar branch of the ulnar artery, branches from the ulnar end of the superficial palmar arch, and the palmar digital artery for the medial border of the little finger.

Innervation

Flexor digiti minimi brevis is innervated by the deep branch of the ulnar nerve, C8 and T1.

Action

Flexor digiti minimi brevis produces flexion of the little finger at its metacarpophalangeal joint, together with some lateral rotation.

Testing

The subject flexes the metacarpophalangeal joint of the little finger while the examiner maintains the interphalangeal joints in extension.

Opponens digiti minimi

Attachments
Opponens digiti minimi is a triangular muscle, lying under cover of the flexor and abductor. It arises from the convexity of the hook of the hamate, and the contiguous portion of the flexor retinaculum, and inserts along the whole length of the ulnar margin of the fifth metacarpal bone, and the adjacent palmar surface.

The muscle is often divided into two lamellae by the deep branches of the ulnar artery and nerve. It blends to a variable degree with its neighbours.

**Relations**

Opponens digiti minimi lies on the ulnar margin and adjacent palmar surface of the fifth metacarpal, overlapped by, and often partly fused with, the other two muscles of the hypothenar eminence.

**Vascular supply**

Opponens digiti minimi is supplied by the deep palmar branch of the ulnar artery, and branches from the medial end of the deep palmar arch.

**Innervation**

Opponens digiti minimi is innervated by the deep branch of the ulnar nerve, C8 and T1.

**Action**

Opponens digiti minimi flexes the fifth metacarpal bone, drawing it forwards and rotating it laterally at the carpometacarpal joint: this deepens the hollow of the palm. These actions, together with flexion and some lateral rotation at the metacarpophalangeal and interphalangeal joints, bring the digit into opposition with the thumb.

**Testing**

The subject is asked to place the tip of the little finger, against resistance, onto the tip of the opposed thumb while the examiner maintains the interphalangeal joints of the little finger in extension.

**Palmaris brevis**

**Attachments**

Palmaris brevis is a thin, quadrilateral muscle, lying beneath the skin of the ulnar side of the palm (see Fig. 50.4). It arises from the flexor retinaculum and the medial border of the central part of the palmar aponeurosis, and is attached to the dermis on the ulnar border of the hand.

**Relations**

Palmaris brevis is superficial to the ulnar artery and the superficial terminal branch of the ulnar nerve.

**Vascular supply**
Palmaris brevis is supplied by branches from the ulnar end of the superficial palmar arch.

**Innervation**

Palmaris brevis is innervated by the superficial branch of the ulnar nerve, C8 and T1.

**Action**

Palmaris brevis wrinkles the skin on the ulnar side of the palm of the hand and deepens the hollow of the palm by accentuating the hypothenar eminence. In this way it may contribute to the security of the palmar grip.

**Testing**

Against resistance, the subject touches the tip of the opposed thumb with the tip of the little finger; the skin on the ulnar side of the palm is seen to pucker.

**Interossei**

The interossei occupy the intervals between the metacarpal bones, and are divided into a palmar and a dorsal set.

*Palmar interossei*

**Attachments**

Palmar interossei are smaller than dorsal interossei and lie on the palmar surfaces of the metacarpal bones rather than between them (Fig. 50.32). With the exception of the first, each of the three arises from the entire length of the metacarpal bone of one finger, and passes to the appropriate (adductor) side of the dorsal digital expansion.
The middle finger has no palmar interosseus. The remaining digits have palmar interossei on their aspects which face the middle finger. The first arises from the ulnar side of the palmar surface of the base of the first metacarpal bone, and is inserted into a sesamoid bone on the ulnar side of the proximal phalanx and from there passes to the phalanx and usually also into the dorsal digital expansion. It lies in front of the lateral head of the first dorsal interosseous, and is overlapped anteriorly by the oblique head of adductor pollicis (Fig. 50.31, Fig. 50.32). It is often very rudimentary because the thumb has its own powerful adductor. The second arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the digital expansion of the index finger. The third arises from the radial side of the fourth
metacarpal bone, and is inserted together with the third lumbrical. The fourth arises from the radial side of the fifth metacarpal bone, and is attached with the fourth lumbrical and also to the base of the proximal phalanx. The attachment of these muscles to the dorsal digital expansions (Fig. 50.30) stabilizes the extensor tendons on the convex heads of the metacarpal bones during flexion and extension at the metacarpophalangeal joints.

The interossei show little variation in their arrangement. They are occasionally reduplicated.

Relations

The first palmar interosseous lies anterior to the lateral head of the first dorsal interosseous and is overlapped anteriorly by the oblique head of adductor pollicis, which also crosses anterior to the second palmar interosseous. The third and fourth are overlapped by the long flexor tendons of the ring and little finger respectively within their flexor sheaths.

Vascular supply

Palmar interossei are supplied by branches from the deep palmar arch, princeps pollicis artery, radialis indicis artery, palmar metacarpal arteries, proximal and distal perforating arteries and common and proper digital (palmar) arteries.

Innervation

All the interossei are innervated by the deep branch of the ulnar nerve, C8 and T1.

Action

Palmar interossei adduct the fingers to an imaginary longitudinal axis through the centre of the middle finger. Interossei have a considerable cross-sectional area and therefore contribute strongly to metacarpophalangeal joint flexion and interphalangeal extension. When paralysed, as in ulnar nerve paralysis, the grip strength of the hand is severely impaired and the arc of finger motion is abnormal, with a tendency for the fingers to claw. Each interosseous has a considerable ability to rotate the digit at the metacarpophalangeal joint. Generally this is not obvious, because interossei act in pairs, but it may occur where one interosseus is deficient as a result of injury or congenital deformity.

Testing

Adduction of the index, ring and little fingers against resistance. The subject grips a piece of paper between the index and middle fingers with the hand placed flat on the table. The examiner can assess the strength of adduction on trying to pull the paper away. This is a reliable test of ulnar nerve integrity.

Dorsal interossei

Attachments

Dorsal interossei consist of four bipennate muscles, each arising from the adjacent sides of two metacarpal bones, but more extensively from the metacarpal bone of the
finger into which the muscle passes (Fig. 50.33). They insert on the bases of the proximal phalanges and separately into the dorsal digital expansions. Between the double origin of each of these muscles there is a narrow triangular interval. The radial artery passes through the first of these intervals, and a perforating branch from the deep palmar arch passes through each of the others. The first and largest muscle is sometimes named abductor indicis. It is attached to the radial side of the proximal phalanx of the index finger and to the capsule of the adjoining metacarpophalangeal joint. The second and third are attached to the radial and ulnar sides of the middle finger, respectively. Whereas the second generally reaches the digital expansion and the proximal phalanx, the third usually extends only to the digital expansion (Fig. 50.30). The fourth may be wholly attached to the digital expansion, but it often sends an additional slip to the proximal phalanx.

Fig. 50.33  Dorsal interossei of the left hand: palmar aspect.  
(From Sobotta 2006.)
Relations

The first dorsal interosseous abuts anteriorly with adductor pollicis. The other dorsal interossei occupy the spaces between the second and the fifth metacarpal bones.

Vascular supply

Dorsal interossei are supplied by the dorsal metacarpal arteries (1st–4th), palmar metacarpal arteries (2nd–4th), radial artery (1st); princeps pollicis artery, radialis indicis artery, three perforating branches from the deep palmar arch (proximal perforating arteries), and three distal perforating branches. The tendons are supplied by branches from the common and proper palmar digital arteries and the dorsal digital arteries.

Innervation

All the interossei are innervated by the deep branch of the ulnar nerve, C8 and T1.

Action

Dorsal interossei abduct the fingers from an imaginary longitudinal axis through the centre of the middle finger. See also Action of palmar interossei.

Testing

Abduction of the index, middle and ring fingers against resistance. Most conveniently, the first dorsal interosseous is tested with the subject's fingers and palm flat upon the table. The subject tries to abduct the index finger against the examiner's resistance. The muscle belly can be felt and seen. This provides a reliable test for the integrity of the ulnar nerve.

Lumbricals

Attachments

The lumbricals are four small fasciculi which arise from the tendons of flexor digitorum profundus (Fig. 50.34). The first and second arise from the radial sides and palmar surfaces of the tendons of the index and middle fingers respectively. The third arises from the adjacent sides of the tendons of the middle and ring fingers, and the fourth from the adjoining sides of the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and is attached to the lateral margin of the dorsal digital expansion of extensor digitorum which covers the dorsal surface of the finger.
Variations in the attachments of the lumbricals are common. Any of them may be unipennate or bipennate. When they are bipennate, the two heads arise from adjoining tendons of flexor digitorum profundus, and, in the case of the first lumbrical, from the tendon of flexor pollicis longus. Accessory lumbrical slips may be attached to an adjacent tendon of flexor digitorum superficialis.

**Vascular supply**

The first and second lumbricals are supplied by the first and second dorsal metacarpal and dorsal digital arteries. The third and fourth lumbricals are supplied by the second and third common palmar digital arteries, and the third and fourth dorsal digital arteries and their anastomoses with the palmar digital arteries.
Innervation

The first and second lumbricals are innervated by the median nerve, C8 and T1, and the third and fourth lumbricals by the deep terminal branch of the ulnar nerve, C8 and T1. The third lumbrical frequently receives a supply from the median nerve. The first and second lumbricals are occasionally innervated by the deep terminal branch of the ulnar nerve.

Action

Lumbricals arise from flexor tendons and insert into the extensor apparatus. Since both attachments are mobile, they have the potential for producing movement at either. The action on the extensor apparatus is easier to understand and consists of extension of both interphalangeal joints in a coordinated manner. The mode of action at the metacarpophalangeal joints is disputed, but if there is a flexor action it is very weak. The effect on the flexor digitorum profundus attachment is to pull the tendon distally. The combined action on both origin and insertion is therefore to alter the posture of the finger to allow more interphalangeal extension. Pinching the index finger against the thumb without a lumbrical would result in a nail-to-nail contact: the addition of the lumbral increases the interphalangeal joint extension, and results in pulp-to-pulp pinch. Lumbricals contain many muscle spindles and have a long fibre length: it is therefore reasonable to assume that they play a role in proprioception.

Testing

Lumbricals cannot be tested in isolation, but the lumbral–interosseous muscle complex can readily be examined together. The examiner holds the metacarpophalangeal joint of the index finger in hyperextension and the subject is instructed to extend the two interphalangeal joints against resistance. This test is repeated seriatim on the middle, ring and little fingers.
COORDINATED MOVEMENTS OF THE HAND

The apparently simple human functions of closing the hand to grasp an object, or opening the palm to release it, are in reality tasks of considerable mechanical complexity, requiring the simultaneous contraction of many individual muscles. The isolated action of a single muscle may be inferred from the positions of its origin and insertion, and the estimated line of action (usually the centre line of the muscle) in relation to the axes of all the joints traversed by the muscle and its tendon. The limb can be regarded as a chain of joints crossed by muscles. If it is known which muscles are active, then the reason why one joint moves and others do not is a matter of simple mechanical relationships.

For example, flexor pollicis longus is considered to have a major role as a flexor of the interphalangeal joint of the thumb. However, the position of its tendon relative to more proximal joints in the limb gives it the potential for producing flexion at the metacarpophalangeal joint and also at the trapeziometacarpal and wrist joints. In the living subject the actual motion that takes place depends on which other muscle groups are acting, and so the potential for movement must be considered for each joint in the chain in turn. Motion at the wrist is generally balanced by wrist extensors. Motion at the trapeziometacarpal joint is balanced by abductor pollicis longus. Flexor pollicis longus will then have an action as a flexor of the metacarpophalangeal and interphalangeal joints only.

The factor that determines whether one or both of two joints will move is the turning moment at each. The greater the perpendicular distance from the line of muscle or tendon pull to the axis of the joint, the stronger is the turning effect of the muscle at the joint, but the smaller the range of joint motion that can be produced. In the case of flexor pollicis longus, the tendon is situated further from the axis of the metacarpophalangeal joint than from the axis of the interphalangeal joint: it will therefore tend to produce flexion preferentially at the metacarpophalangeal joint unless that joint is restrained by extensor pollicis brevis. In this way different postures of the thumb can be produced by the interplay of flexor and extensor forces. These simple guiding principles should provide an understanding of muscle action in the hand that is sufficient for most purposes.

In considering the role of a particular muscle, there is a tendency to concentrate on motion. Indeed, many muscles are named on the basis of the movements that they generate, although others – often those whose actions are the most difficult to interpret – are described according to their morphology or situation. A more important function may be the nature of the force generated. For example, although flexor pollicis longus flexes the thumb (see above), a large range of flexion is actually required in only a few activities, such as certain ripping tasks. In most pinch and manipulative tasks
the role of the thumb is to apply isometric force, which it does with such precision that it is possible to pick up an egg and neither crush nor drop it. Thus for much of the time flexor pollicis longus behaves as an extremely sophisticated mechanism for the application of force, in which contraction and proprioception are equally important.

The anatomical position of the hand (palm flat and pointing anteriorly, forearm supinated) is a convenient standard for studying structural relationships. The hand in the relaxed (anaesthetized) position adopts a posture of partial flexion and mid-supination/pronation (the reader can verify this by relaxing completely and observing forearm and hand position).
SPECIAL FUNCTIONS OF THE HAND

Closing the hand

It is clear that the fingers and palm of the hand flex in gripping, grasping or making a fist, but there are subtle differences in hand posture in these various activities. The basic mechanisms of hand closure will be described before special grips are considered.

As the digits flex, the wrist usually extends (dorsiflexes) at the same time. The involvement of the long digital flexors in this movement will be considered first, followed by an analysis of the role of the wrist.

Role of the long digital flexors

Flexor digitorum superficialis acts principally to flex the proximal interphalangeal joints, through its insertions into the middle phalanges. However, in each digit it also has an action on the metacarpophalangeal joint, because the tendon passes anterior to that joint. The muscle has the potential to produce flexion at the wrist for the same reason. The fact that each tendon arises from an individual muscle slip allows the clinician to test one finger at a time. The reader can verify this by attempting to flex each digit individually while using the other hand to keep the distal interphalangeal joints of the remaining fingers in extension. This test is frequently used in clinical practice and is useful for the middle and ring fingers, where flexion of one finger alone must be attributed to flexor digitorum superficialis. The index finger, however, has its own profundus musculotendinous unit and may therefore move independently under the action of this tendon. Many individuals cannot flex the proximal interphalangeal joint of the little finger alone; usually this is because of linkage between the ring and little finger flexor digitorum superficialis tendons, but occasionally may be because superficialis is deficient. Most individuals can flex the metacarpophalangeal joint of the little finger using flexor digiti minimi.

Flexor digitorum profundus reaches further (to the distal phalanx), and is therefore the only muscle available for flexion of the distal interphalangeal joint. It also contributes, together with superficialis, to flexion at the proximal interphalangeal and metacarpophalangeal joints. These two long flexors (sometimes called extrinsic flexors, because the muscle bellies are outside the hand) can be considered to act together to flex the finger. However, their action alone would wind up the interphalangeal before the metacarpophalangeal joints and the finger would not move in a normal arc of flexion. This is precisely what happens in an ulnar nerve paralysis, in which the interossei and lumbricals are not functioning. These small (intrinsic) muscles have been described earlier in terms of their individual actions. For their role in coordinated activity it is sufficient to appreciate that their contribution changes the arc produced by the long flexors, increasing flexion at the metacarpophalangeal joint and reducing flexion at the proximal interphalangeal joint. All three joints are then angulated to the same degree and the fingers form a normal arc of flexion. As the finger flexes, the long extensor tendons (extensor digitorum, extensor indicis and extensor digiti minimi) aid the process by relaxing and allowing the extensor apparatus to glide distally on the dorsum of the phalanges. (See also p. 879.)

Role of the wrist
As the fingers wind up to make a fist, the wrist tends to extend, particularly when force is applied. This extension has a marked effect on the excursion of the long flexor tendons. On its own, digital flexion would require the long tendons to move proximally in their sheaths and the flexor muscles in the forearm would shorten. Extension of the wrist tends to produce a lengthening of the same muscles, which in normal use is almost enough to balance the shortening due to finger flexion; the net effect is a very slight shortening (approximately 1 cm) of the long flexors in the forearm. The wrist can therefore be seen as a mechanism for maximizing force, because it allows the fingers to flex while maintaining the resting length of the extrinsic muscles near to the peak of the force–length curve. It is, of course, possible to wind up the fingers with the wrist held in a neutral position, but the grip is somewhat weaker. With the wrist in full flexion it is not possible to flex the fingers fully.

Flexion of the fingers on gripping tends to result in a distal excursion of the long extensors. However, this tendency is counteracted by dorsiflexion of the wrist. The net effect is a very small proximal excursion of the long extensor tendons on gripping, mirroring the effect on the flexor surface. If the movement of the wrist is exaggerated so that the wrist is a little flexed on opening the hand, and fully dorsiflexed on closing it, the net excursion of long flexors and extensors is zero, i.e. this whole movement sequence can be completed with the forearm flexor and extensor muscles contracting isometrically.

The reader can observe the relationship between digits and wrist by performing the following manoeuvre. The wrist is held in a relaxed, mid-supinated position, with the elbow flexed at 90°. If the forearm is now rotated into pronation, the wrist will fall into flexion and the fingers will automatically extend. If the forearm is rotated into supination, the wrist will extend and the fingers flex. The finger movements compensate for the wrist movements and are entirely automatic; they are made without the need for any excursion of forearm flexor or extensor tendons. This test, the wrist tenodesis test, is a useful way of examining the limb for tendon injury. The pointing finger (which does not move with wrist motion) ‘points to’ a tendon injury.

Wrist motion is controlled principally by two wrist flexors (flexor carpi radialis and flexor carpi ulnaris) and three extensors (extensores carpi radialis longus and brevis, and extensor carpi ulnaris). Although the radiocarpal joint has some functional similarity to a ball and socket joint, it is possible to think of the wrist as a variable hinge joint, the axis of which may be set in a number of inclinations. For example, in using a hammer it is useful to rotate the wrist backwards and forwards about an axis that permits not only wrist flexion but also ulnar deviation. It would be very restricting to have a pure hinge joint with collateral ligaments of fixed length. In this context, the wrist flexors and extensors may be regarded as variable collateral ligaments which allow the joint to be set about a number of different axes.

For movement about major axes, the wrist tendons can be considered to act in pairs: flexores carpi radialis and carpi ulnaris produce wrist flexion; extensores carpi radialis longus and brevis, and extensor carpi ulnaris produce wrist extension; extensor carpi ulnaris and flexor carpi ulnaris produce ulnar deviation; flexor carpi radialis, extensores carpi radialis longus and brevis, extensor policis and abductor policis longus produce radial deviations. (See also p. 871.)
It is possible to observe and to palpate the muscle groups that are active in making a tight fist. The flexor compartment of the forearm is contracted tightly and electromyogram evidence confirms that flexor digitorum profundus and flexor digitorum superficialis are active. Flexor carpi ulnaris may be seen and felt to contract strongly. The extensor compartment is tightly contracted and the wrist extensors would certainly be expected to be active. Palpation of the long digital extensors on the back of the wrist will show these to be contracting as well. It seems that when the fingers are held tightly closed, the long digital extensors are unable to move the extensor apparatus: they have acquired a new fixed point on which to act, namely the proximal limit of the extensor apparatus over the metacarpophalangeal joint. They therefore perform the only task available to them and act together as an additional wrist extensor.

In the thumb web, palpation confirms that the first dorsal interosseous is contracting, as are all the other interossei and the thenar and hypothenar muscles. As the firm fist is swung forward in anger the brachioradialis stands out, and at the moment of impact virtually every muscle in the limb is in a state of contraction, with the exception of the lumbricals.

Opening the hand

The hand is opened from its relaxed balanced posture, e.g. when stretching out to reach an object. This motion is made up of extension of the distal interphalangeal, proximal interphalangeal and metacarpophalangeal joints. The hand is provided with an ingenious mechanism that allows this to happen. The laws of mechanics would suggest that one motor would be required for every joint in a chain, together with some sort of controlling mechanism to ensure that the chain of joints moved together in a coordinated fashion. In the hand this is achieved through an extensor apparatus which minimizes the number of motors required for movement by allowing the muscles to act on more than one joint, and by linking different levels in the mechanism so that the arc of motion is controlled.

The tendons of extensor digitorum run distally over the metacarpal heads, forming the major component of the extensor apparatus. Extensor digitorum has no insertion into the proximal phalanx and therefore exerts its extensor action on the metacarpophalangeal joint indirectly through more distal insertions. The first point of insertion is at the base of the middle phalanx (in clinical practice the term central slip has been adopted). Acting at this insertion alone, extensor digitorum can extend both metacarpophalangeal and proximal interphalangeal joints together. The interossei are also active in hand opening, since they will tend to increase extension of the proximal interphalangeal joint. There is therefore a range of possibilities. At one extreme, with no interosseous contribution, the long extensor will exert all of its action at the metacarpophalangeal joint: this leads to full extension, and even hyperextension, while the proximal interphalangeal joint remains flexed (the typical claw hand of ulnar nerve paralysis, or ‘intrinsic minus’ hand). At the other extreme, when the intrinsics act strongly together with extensor digitorum, the proximal interphalangeal joint will extend completely while the metacarpophalangeal joint remains flexed (‘intrinsic plus’ hand). Thus the hand possesses in the proximal part of the extensor apparatus a variable mechanism that allows different amounts of relative metacarpophalangeal or proximal interphalangeal joint motion.
In contrast, the more distal part of the extensor apparatus acts as an automatic or fixed mechanism which determines that the two interphalangeal joints, proximal and distal, will move together. The lateral slips of the extensor apparatus arise from extensor digitorum and pass distally on either side of the central slip and thus over the proximal interphalangeal joint: being further lateral, they are nearer the joint axis, because the dorsal surface curves away on each side. A helpful analogy that has been suggested for this arrangement is to consider it as two pulleys of different size on one axle. The central slip can be regarded as a cord that passes over the larger wheel, and each lateral slip as a cord that passes over the smaller wheel. Since these latter pulleys are smaller there is less longitudinal excursion for a given rotation of the wheel, and this allows some of the excursion to be used for another function, namely extension at the distal joint. There is an additional mechanism by which the lateral slips move laterally during flexion of the proximal interphalangeal joint. The effect of this lateral movement is to reduce further the distance between the lateral slips and the joint axis, thereby reducing the amount of excursion at the proximal interphalangeal joint still more and allowing more excursion at the distal joint. When the hand flexes, this mechanical linkage system allows both interphalangeal joints to flex together in a coordinated way.

The extensor expansion also receives contributions from the interossei and lumbricals, which approach the digits from the webs and join the corresponding expansion in the proximal segment of the digit. These small muscles can therefore act on the extensor apparatus at two levels: they can extend the proximal interphalangeal joint through fibres that radiate towards the central slip, and they can act on the distal interphalangeal joint through fibres that join the lateral slip.

Apart from the components of the extensor expansion that are concerned with joint function, the whole structure requires additional anchorage. This must be arranged in such a way that it is not displaced from the underlying skeleton, yet it must not restrict longitudinal movement. These difficult requirements are met by transverse retinacular ligaments at the level of the joints, the transverse ligaments running to relatively fixed attachment points in the region of the joint axis. As the expansion glides backwards and forwards the transverse fibres move like bucket handles. Smooth gliding layers are required under the expansion and retinacular ligaments to allow motion to occur without friction.

One final component of the extensor apparatus provides an additional automatic function. This is a fibrous anchorage system, Landsmeer's oblique retinacular ligament, which anchors the distal expansion to the middle phalanx. The role of the oblique retinacular ligament is controversial (reviewed by Bendz 1985). Some argue it may act in a dynamic tenodesis effect to synchronize the movements of the interphalangeal joints, i.e. it may initiate extension of the distal interphalangeal joint as the proximal interphalangeal joint is extended from a fully flexed position, and relax with proximal interphalangeal joint flexion to allow full distal interphalangeal joint flexion. Others argue that it only becomes taut when the proximal interphalangeal joint is fully extended and the distal interphalangeal joint is flexed, so that it functions as a restraining force to stabilize the fingertip when it is flexed against resistance, e.g. in the hook grip. A further suggestion is that the ligament is merely a secondary lateral stabilizer of the proximal interphalangeal joint and that it acts to centralize the extensor components over the dorsum of the middle phalanx.
**Movements of the thumb**

An opposable thumb requires a different system of control from the other digits. Since the metacarpal is much more mobile than in the digits, muscles are needed to control the extra freedom of movement.

The thumb does not easily assume the classical anatomical position. Therefore the normal descriptive anatomical terms – anterior, posterior, medial and lateral – do not readily apply. The terms ‘palmar, dorsal, ulnar and radial’ have been adopted in clinical practice.

The basic active movements are flexion–extension, abduction–adduction, rotation, and circumduction. In the resting position of the first metacarpal, flexion and extension are parallel with the palmar plane, and abduction and adduction occur at right angles to this.

Flexion and extension should be confined to motion at the interphalangeal or metacarpophalangeal joints (Fig. 50.35A–C). Palmar abduction (Fig. 50.35D,E), in which the first metacarpal moves away from the second at right angles to the plane of the palm, and radial abduction (Fig. 50.35D,F), in which the first metacarpal moves away from the second with the thumb in the plane of the palm, occur at the carpometacarpal joint. The opposite of radial abduction is ulnar adduction, or transpalmar adduction, in which the thumb crosses the palm towards its ulnar border. In clinical practice the term adduction is generally used without qualification.

Circumduction describes the angular motion of the first metacarpal, solely at the carpometacarpal joint, from a position of maximal radial abduction in the plane of the palm towards the ulnar border of the hand, maintaining the widest possible angle between the first and second metacarpals (Fig. 50.35G). Lateral inclinations of the first phalanx maximize the extent of excursion of the circumduction arc. Opposition is a composite position of the thumb achieved by circumduction of the first metacarpal, internal rotation of the thumb ray and maximal extension of the metacarpophalangeal and interphalangeal joints (Fig. 50.35H). Retroposition is the opposite to opposition (Fig. 50.35I). Flexion and adduction is the position of maximal transpalmar adduction of the first metacarpal: the metacarpophalangeal and interphalangeal joints are flexed and the thumb is in contact with the palm (Fig. 50.35J).
Rotary movements occur during circumduction. The simple angular movements described above combine with rotation about the long axis of the metacarpal shaft. In opposition, the shaft must rotate medially into pronation. In retroposition, the thumb must rotate laterally into supination. Axial rotation of the thumb metacarpal is produced by muscle activity (which moves the thumb through its arc of circumduction); the geometry of the articular surfaces of the trapeziometacarpal joint; tensile forces in the ligaments (which combine with forces exerted by the muscles of opposition and retroposition to produce axial rotation). The stability of the first metacarpal is greatest after complete pronation in the position of full opposition, when ligamentary tension, muscular contraction and joint congruence combine to maximal effect. (See also p. 875.)
Position of rest

The hand has a well-recognized position of rest, with the wrist in extension and the digits in some degree of flexion. The precise position of the thumb in the position of rest appears to be rather variable. Typically it is considered as the midpoint between maximal palmar abduction and maximal retroposition. In this position the carpometacarpal joint lies within 20° of radial abduction and 30° of palmar abduction, and from clinical observations it seems that the metacarpophalangeal joint lies within approximately 40° of flexion and the interphalangeal joint between extension and 10° of flexion.

Grips

From the position of rest, the tip of the thumb can approach the radial aspect of the fingers without incurring axial rotation because the palmar and dorsal trapeziometacarpal ligaments remain relaxed (see below).

From different positions of the arc of circumduction, numerous different types of pinch grip are possible (Fig. 50.36). In clinical practice these have been classified into two main types: tip pinch and lateral (or key) pinch. Many forces contribute to these configurations.
The thumb is a triarticular system, unlike the finger, which is a biarticular system. The thumb is activated by monoarticular muscles (abductor pollicis longus and opponens pollicis), biarticular muscles (extensor pollicis brevis, adductor pollicis, abductor pollicis brevis and flexor pollicis brevis), and triarticular muscles (extensor pollicis longus and flexor pollicis longus). It appears, however, that even a monoarticular muscle can change posture in all three joints by altering the overall balance of forces, and it is therefore very difficult to attribute function to the individual intrinsic muscles. However, the thumb muscles do seem to provide two broad functions. They control metacarpal positioning (the guy-rope function), an activity that is automatically accompanied by rotation. They also control the axial stability of the skeleton of the thumb.

The thumb muscles can be classified into those used for retroposition, opposition and pinch grip.

Retroposition muscles

The muscles that bring about retroposition are extensor pollicis longus, extensor pollicis brevis and abductor pollicis longus. As the thumb moves into retroposition, automatic axial rotation produces supination of the first metacarpal. This is produced by the off-axis action of two parallel, but oppositely directed, forces, one exerted by extensores pollicis longus and brevis and the other by abductor pollicis longus and the anterior oblique carpometacarpal ligament.
Opposition muscles

A succession of activity occurs in the thenar muscles during the movement of opposition. Three subgroups of radial (abductor pollicis longus and extensor pollicis brevis), central (abductor pollicis brevis and opponens pollicis) and ulnar (flexor pollicis brevis) muscles are involved. These forces act simultaneously but with different intensities, depending on the situation of the thumb. As the thumb moves into opposition there is automatic axial rotation of the first metacarpal shaft to produce pronation. This is produced by the paired action of oppositely directed forces: the opposition muscles provide one force, and the posterior oblique carpometacarpal ligament provides the other.

Pinch grip muscles

The muscles of pinch grip can be divided into lateral, medial and intermediate subgroups. The lateral subgroup (opposition muscles) moves the first metacarpal into palmar abduction. The metacarpal shaft rotates medially into pronation. Radial angulation at the metacarpophalangeal joint increases the span of the hand. The metacarpophalangeal joint is stabilized principally by extensor pollicis brevis and flexor pollicis brevis. Flexion of the proximal and distal phalanges is controlled. Muscles of the medial subgroup (abductor pollicis brevis and first dorsal interosseous) produce an approach of the first metacarpal towards the palm. Since they act with the lateral group they have a strong controlling effect on the position and rotation of the first metacarpal. The intermediate subgroup consists simply of flexor pollicis longus, which flexes the interphalangeal or metacarpophalangeal joint, as described earlier. Palpating the thenar eminence during tip and lateral pinch provides some appreciation of the action of the pinch grip muscles.
**VASCULAR SUPPLY AND LYMPHATIC DRAINAGE**

**ARTERIES**

Anastomoses occur between the radial and ulnar arteries at the wrist (via the palmar and dorsal carpal arches) and in the hand (via the superficial and deep palmar arches), and between their digital and metacarpal branches.

Radial artery

At the wrist the radial artery passes on to the dorsal aspect of the carpus between the lateral carpal ligament and the tendons of abductor pollicis longus and extensor pollicis brevis (Fig. 50.37). It crosses the scaphoid bone and trapezium (in the ‘anatomical snuff-box’), where again its pulsation is obvious, and as it passes between the heads of the first dorsal interosseous it is crossed by the tendon of extensor pollicis longus. Between the thumb extensors it is crossed by the start of the cephalic vein and the digital branches of the radial nerve which supply the thumb and index finger (Fig. 50.38). Occasionally it gives off a distal superficial dorsal branch which crosses the radial extensor tendons at the wrist together with the superficial radial nerve. Filaments of the lateral cutaneous nerve of the forearm run along its distal part as it curves round the carpus.
Fig. 50.37: Superficial structures of the left palm and wrist. See also Fig. 50.26.
In the hand the radial artery passes through the first interosseous space between the heads of the first dorsal interosseous and crosses the palm. At first it lies deep to the oblique head of adductor pollicis and then passes between its oblique and transverse heads or through the transverse head. At the fifth metacarpal base it anastomoses with the deep branch of the ulnar artery, completing the deep palmar arch (Fig. 50.39).
Palmar carpal branch

The palmar carpal branch is a small vessel which arises from the radial artery near the distal border of pronator quadratus (Fig. 50.40). It crosses the anterior surface of the distal end of the radius, near the palmar carpal surface, and passes medially to anastomose behind the long flexor tendons with the palmar carpal branch of the ulnar artery. This transverse anastomosis is joined by longitudinal branches from the anterior interosseous artery and recurrent branches from the deep palmar arch, to form a cruciate palmar carpal arch which supplies the carpal articulations and bones by descending branches. (Although so named, this anastomosis is usually sited near the wrist joint on the distal forearm bones.)
Superficial palmar branch

The superficial palmar branch arises from the radial artery just before it curves round the carpus. It passes through, and occasionally over, the thenar muscles, which it supplies, sometimes anastomosing with the end of the ulnar artery to complete a superficial palmar arch (Fig. 50.39).

Dorsal carpal branch

The dorsal carpal branch arises deep to the thumb extensor tendons. It runs medially across the dorsal carpal surface under them and anastomoses with the ulnar dorsal carpal branch and also with the anterior and posterior interosseous arteries to form a dorsal carpal arch. The carpal arches are both close to bone and supply the distal epiphyseal parts of the radius and ulna. From the dorsal arch three dorsal metacarpal arteries descend on the second to fourth dorsal interossei and bifurcate into the dorsal digital branches to supply the adjacent sides of all four fingers.

First dorsal metacarpal artery

The first dorsal metacarpal artery arises from the radial artery just before it passes between the heads of the first dorsal interosseous (Fig. 50.2). It divides almost at once into two branches which supply the adjacent sides of the thumb and index finger as far distally as the proximal interphalangeal joint. The radial side of the thumb receives a branch direct from the radial artery proper.

In the majority of cases the first dorsal metacarpal artery follows a fascial course overlying the first dorsal interosseous and parallel to the second metacarpal bone. Occasionally it may follow an intramuscular course. Distally, over the proximal phalanx, it anastomoses with the dorsal branches of the radiopalmar digital artery of the index finger. In a small number of cases, the first dorsal interosseous artery either arises from, or gives rise to, an ulnordorsal digital artery of the thumb. Occasionally it gives rise to the ulnopalmar digital artery of the thumb, and rarely may give rise to the second dorsal metacarpal artery.

The usual anatomical arrangement allows a flap of skin over the dorsum of the proximal phalanx of the index finger to be raised on this artery and its accompanying venae comitantes. This is particularly useful under certain circumstances for reconstruction of the thumb following injury.

Second, third and fourth dorsal metacarpal arteries

The second to fourth dorsal metacarpal arteries arise from the dorsal carpal arch. Near their origins they anastomose with the deep palmar arch by proximal perforating arteries and, near their bifurcation, with dorsal perforating branches from the palmar metacarpal arteries which pass between the metacarpal necks. They also anastomose distally at the level of the web spaces with dorsal perforating branches.
from the palmar digital arteries from the superficial palmar arch. The third and fourth dorsal metacarpal arteries are much smaller than the first and second.

Cutaneous branches from the dorsal metacarpal arteries supply the dorsal skin as far distally as the proximal interphalangeal joint. At the level of the neck of the second, third and fourth metacarpals, a direct cutaneous branch is given off which passes proximally and supplies an area of skin between the two adjacent metacarpals (Fig. 50.41).

These anatomical arrangements permit the surgical elevation of flaps of dorsal skin to be based either proximally on the dorsal metacarpal arteries proper, or distally on the direct cutaneous branch. These flaps may be used for reconstructing areas of missing tissue elsewhere in the hand.

Arteria princeps pollicis

The arteria princeps pollicis arises from the radial artery as it turns into the palm to form the deep palmar arch. It descends on the palmar aspect of the first metacarpal under the oblique head of adductor pollicis lateral to the first palmar interosseous. At the base of the proximal phalanx, deep to the tendon of flexor pollicis longus, the
artery divides into two branches. It appears between the medial and lateral attachments of the oblique head of adductor pollicis to run along both sides of the thumb. On the palmar surface of its distal phalanx it forms a pollicial arch which supplies the skin and subcutaneous tissue. The arteria princeps pollicis is the usual nutrient of supply to the first metacarpal bone.

Arteria radialis indicis

The arteria radialis indicis is often a proximal branch of the arteria princeps pollicis. It descends between the first dorsal interosseous and transverse head of adductor pollicis, and along the lateral side of the index finger to its end (Fig. 50.37). It anastomoses with the indicial medial digital artery. At the distal border of the transverse head of adductor pollicis it anastomoses with the arteria princeps pollicis and links with the superficial palmar arch. It may arise from the superficial arch or from the first dorsal metacarpal artery.

The arteria princeps pollicis and radialis indicis may be combined as the first palmar metacarpal artery.

Deep palmar arch

The deep palmar arch is formed by anastomosis of the end of the radial artery with the deep palmar branch of the ulnar artery (Fig. 50.39 and Fig. 50.42A). It crosses the bases of the metacarpal bones and interossei, covered by the oblique head of adductor pollicis, the digital flexor tendons and lumbricals. In its concavity, running laterally, is the deep branch of the ulnar nerve. Rarely the arch is incomplete. There are variations in the size of contribution from the ulnar artery.

Palmar metacarpal artery

The three palmar metacarpal arteries run distally from the convexity of the deep palmar arch on the interossei of the second to fourth spaces, and join the common digital branches of the superficial arch at the digital clefts (Fig. 50.39). They supply nutrient branches to the medial four metacarpals.

Perforating branches

Three perforating branches from the deep palmar arch cross the second to fourth interosseous spaces between the heads of the corresponding dorsal interossei and anastomose with the dorsal metacarpal arteries.

Recurrent branches

Recurrent branches ascend proximally from the deep palmar arch anterior to the carpus to supply the carpal bones and intercarpal articulations. They end in the palmar carpal arch.

Ulnar artery

At the wrist the ulnar artery (Figs 50.37 and 50.39) is covered by skin, fasciae and palmaris brevis. It lies between the superficial and main parts of the flexor retinaculum, lateral to the ulnar nerve and pisiform.

Dorsal cutaneous branch

A constant dorsoulnar perforator vessel is given off distally. It arises 2–5 cm proximal to the pisiform and accompanies the dorsal cutaneous branch of the ulnar nerve. It emerges between flexor carpi ulnaris and extensor carpi ulnaris. The cutaneous perforator can support a flap of skin on the medial aspect of the distal forearm just proximal to the wrist and is useful in reconstructing areas of missing skin in this region.

Palmar carpal branch

A small palmar carpal branch crosses the distal ulna deep to the tendons of flexor digitorum profundus (Fig. 50.40), and anastomoses with a palmar carpal branch of the radial artery to make a palmar carpal arch.

Dorsal carpal branch

A dorsal carpal branch arises just proximal to the pisiform (Fig. 50.40). It curves deep to the tendon of flexor carpi ulnaris to reach the carpal dorsum, which it crosses laterally beneath the extensor tendons. It anastomoses with the dorsal carpal branch of the radial artery to complete the dorsal carpal arch. Near its origin it sends a small
digital branch along the ulnar side of the fifth metacarpal to supply the medial side of the dorsal surface of the fifth finger.

**Deep palmar branch**

The deep palmar branch is often double (Fig. 50.40). It passes between abductor and flexor digiti minimi, through or deep to opponens digiti minimi. It anastomoses with the radial artery, completing the deep palmar arch. The deep palmar branch accompanies the deep branch of the ulnar nerve.

**Superficial palmar arch**

The superficial palmar arch is an anastomosis fed mainly by the ulnar artery (Figs 50.2 and 50.39). The latter enters the palm with the ulnar nerve, anterior to the flexor retinaculum and lateral to the pisiform. It passes medial to the hook of the hamate, then curves laterally to form an arch that is convex distally and level with a transverse line through the distal border of the fully extended pollicial base. About a third of the superficial palmar arches are formed by the ulnar artery alone; a further third are completed by the superficial palmar branch of the radial artery; and a third by the arteria radialis indicis, a branch of either arteria princeps pollicis or the median artery. The superficial palmar arch is covered by palmaris brevis and the palmar aponeurosis and it is superficial to flexor digiti minimi, branches of the median nerve and the long flexor tendons and lumbricals.

**Common and proper palmar digital arteries**

Three common palmar digital arteries arise from the convexity of the superficial palmar arch (Fig. 50.39). They pass distally on the second to fourth lumbricals, each joined by a corresponding palmar metacarpal artery from the deep palmar arch, and divide into two proper palmar digital arteries. These run along the contiguous sides of all four fingers, dorsal to the digital nerves, between Grayson's and Cleland's ligaments, anastomosing in the subcutaneous tissue of the finger tips and near the interphalangeal joints. Each digital artery has two dorsal branches which anastomose with the dorsal digital arteries and supply the soft parts dorsal to the middle and distal phalanges, including the matrices of the nails. The palmar digital artery for the medial side of the little finger leaves the arch under palmaris brevis. Palmar digital arteries supply the metacarpophalangeal and interphalangeal joints and nutrient rami to the phalanges. They are the main digital supply, because the dorsal digital arteries are minute.

The origins of the palmar digital arteries of the thumb are quite variable. Both may arise from a single princeps pollicis, or they may arise separately from the superficial palmar arch. The ulnar digital artery may arise from the first dorsal metacarpal artery.

The terminal branches of the digital arteries contribute to a number of vascular arcades which provide a rich vascular supply for the distal elements of each digit (Fig. 50.43). Three distal phalangeal dorsal arterial arcades anastomose with each other and with those from the other side of the digit. The superficial arcade occurs at the level of the proximal nailfold and is supplied primarily by a dorsal branch from the palmar digital artery, which is given off at the level of the middle phalanx. The proximal subungual arcade is at the level of the lunula and is supplied by a terminal branch of the digital artery, which passes dorsally. The distal subungual arcade occurs more
distally in the nail bed. It is supplied by a dorsal vessel which emerges from the point of confluence of the ‘H’-shaped anastomosis between the terminal portions of both digital arteries, and passes from volar to dorsal aspect of the digit under the interosseous ligament which connects the proximal and distal parts of the distal phalanx (Fig. 50.43).

![Fig. 50.43 Terminal vascular arcades over the distal phalanx.](By permission from Flint MH 1956 Some observations on the vascular supply of the nail bed and terminal segments of the fingers. BJPS 8: 186–95.)

Glomus tumours

Glomus tumours are very painful (often tiny and sometimes difficult to identify) tumours of the glomus bodies (small AV anastomoses involved in the regulation of
peripheral skin temperature control; see Fig. 6.16). These typically occur in the proximal nailfold/subungual regions of the finger tips in association with the dorsal digital arterial arcades, although they can occur anywhere. They are diagnosed by exquisite point tenderness over the swelling with reduction of tenderness when the finger is exsanguinated. If the tumour is not visible (as is often the case) then the best way surgically to explore the dorsal fingertip region to look for the tumour is to incise the lateral nailfold and hyponychium and raise this as a flap along with the underlying periosteum pedicled on the blood supply from the opposite nailfold. The dorsal distal phalangeal digital arterial arcades are then identified from their deep surface and any glomus tumour identified.
**VEINS**

*Superficial veins of the hand*

**Dorsal and palmar digital veins**

Dorsal digital veins pass along the sides of the fingers, joined by oblique branches. They unite from the adjacent sides of the digits into three dorsal metacarpal veins (Fig. 50.44), which form a dorsal venous network over the metacarpus. This is joined laterally by a dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the thumb, and is prolonged proximally as the cephalic vein (Fig. 50.42). Medially a dorsal digital vein from the ulnar side of minimus joins the network, which ultimately drains proximally into the basilic vein. A vein often connects the central parts of the network to the cephalic vein near the midforearm.
The veins of the dorsum of the hand. (From Sobotta 2006.)

Palmar digital veins connect to their dorsal counterparts by oblique intercapitular veins which pass between metacarpal heads. They also drain to a plexus superficial to the palmar aponeurosis, extending over both thenar and hypothenar regions.

Cephalic vein
The cephalic vein forms over the anatomical snuff-box from the radial extremity of the dorsal venous plexus. It runs proximally over the distal lateral aspect of the radius, where it is easily visible.

**Deep veins of the hand**

**Superior and deep palmar venous arches**

Superficial and deep palmar venous arches accompany their arterial counterparts and receive the corresponding branches. Thus common palmar digital veins join the superficial arch, and palmar metacarpal veins join the deep arch.

**Palmar and dorsal metacarpal veins**

Deep veins accompanying the dorsal metacarpal arteries receive perforating branches from the palmar metacarpal veins. They end in the radial veins and the dorsal venous network over the metacarpus. This network is joined laterally by a dorsal digital vein from the radial side of the index finger and by both digital veins of the thumb, and is prolonged proximally as the cephalic vein.
INNERVATION

Median nerve

The median nerve proximal to the flexor retinaculum is lateral to the tendons of flexor digitorum superficialis and lies between the tendons of flexor carpi radialis and palmaris longus (Fig. 50.45A). It passes under the retinaculum in the 'carpal tunnel' where it may be compressed in the carpal tunnel syndrome (see p. 897). Distal to the retinaculum the nerve enlarges and flattens, and usually divides into five or six branches: the mode and level of division are variable.

_palmar cutaneous branch_

The palmar cutaneous branch starts about 3 cm proximal to the flexor retinaculum. It runs in a small tunnel in the sheath of flexor carpi radialis before piercing the deep fascia where it divides into lateral branches that supply the thenar skin and connect with the lateral cutaneous nerve of the forearm. Medial branches supply the central palmar skin and connect with the palmar cutaneous branch of the ulnar nerve.

Communicating branches, which may be multiple, often arise in the proximal forearm, sometimes from the anterior interosseous branch. They pass medially between flexores digitorum superficialis and profundus and behind the ulnar artery to join the ulnar nerve. This communication is a factor in explaining anomalous muscular innervation in the hand (see below).

Muscular branch (motor or recurrent branch)

The muscular branch is short and thick, and arises from the lateral side of the nerve; it may be the first palmar branch or a terminal branch which arises level with the digital branches. It runs laterally, just distal to the flexor retinaculum, with a slight recurrent curve beneath the part of the palmar aponeurosis covering the thenar muscles (Fig. 50.45A). It turns round the distal border of the retinaculum to lie superficial to flexor pollicis brevis, which it usually supplies, and continues either superficial to the muscle or traverses it. It gives a branch to abductor pollicis brevis, which enters the medial edge of the muscle, and then passes deep to it to supply opponens pollicis, entering its medial edge. Its terminal part occasionally gives a branch to the first dorsal interosseous, and may be its sole or partial supply. The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum, a point of surgical importance.

Palmar digital branches

The median nerve usually divides into four or five digital branches (Fig. 50.45A). It often divides first into a lateral ramus which provides digital branches to the thumb and the radial side of the index finger, and a medial ramus, which supplies digital branches to adjacent sides of the index, middle and ring fingers. Other modes of termination can occur.

Digital branches are commonly arranged as follows. They pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the long flexor tendons. Two proper palmar digital nerves, sometimes from a common stem, pass to the sides of the thumb: the nerve supplying its radial side crosses in front of the tendon of flexor pollicis longus. The proper palmar digital nerve to the lateral side of
the index also supplies the first lumbrical. Two common palmar digital nerves pass
distally between the long flexor tendons. The lateral divides in the distal palm into two
proper palmar digital nerves which traverse adjacent sides of the index and middle
finger. The medial divides into two proper palmar digital nerves which supply adjacent
sides of the middle and ring fingers. The lateral common digital nerve supplies the
second lumbrical, and the medial receives a communicating twig from the common
palmar digital branch of the ulnar nerve and may supply the third lumbrical. In the
distal part of the palm the digital arteries pass deeply between the divisions of the
digital nerves: the nerves lie anterior to the arteries on the sides of the digits. The
median nerve usually supplies palmar cutaneous digital branches to the radial three
and one-half digits (thumb, index, middle and the lateral side of the ring): sometimes
the radial side of the ring finger is supplied by the ulnar nerve. Occasionally, there is a
communicating branch between the common digital nerve to the middle and ring
fingers (derived from the median nerve) and the common digital nerve to the ring and
little fingers (derived from the ulnar nerve): this can explain variations in sensory
patterns that do not conform to the classic pattern.

The proper palmar digital nerves pass along the medial side of the index finger, and
both sides of the middle and the lateral side of the ring finger. They enter these digits
in fat between slips of the palmar aponeurosis. Together with the lumbricals and
palmar digital arteries, they pass dorsal to the superficial transverse metacarpal
ligament and ventral to the deep transverse metacarpal ligament. In the digits, the
nerves run distally beside the long flexor tendons (outside their fibrous sheaths), level
with the anterior phalangeal surfaces and anterior to the digital arteries, between
Grayson's and Cleland's ligaments. Each nerve gives off several branches to the skin
on the front and sides of the digit (where many end in Pacinian corpuscles), and
sends branches to the metacarpophalangeal and interphalangeal joints.

The digital nerves supply the fibrous sheaths of the long flexor tendons, digital arteries
(vasomotor) and sweat glands (secretomotor). Distal to the base of the distal phalanx
each digital nerve gives off a branch which passes dorsally to the nail bed. The main
erve frequently trifurcates to supply the pulp and skin of the terminal part of the digit.
Distal to the base of the proximal phalanx, each proper digital nerve also gives off a
dorsal branch to supply the skin over the back of the middle and distal phalanges. The
proper palmar digital nerves to the thumb and the lateral side of the index finger
emerge with the long flexor tendons from under the lateral edge of the palmar
aponeurosis. They are arranged in the digits as described above, but in the thumb
small distal branches supply the skin on the back of the distal phalanx only.

Other branches

In addition to the branches of the median nerve described above, variable vasomotor
branches supply the radial and ulnar arteries and their branches. Some of the
intercarpal, carpometacarpal and intermetacarpal joints are said to be supplied by the
median nerve or its anterior interosseous branch: the precise details are uncertain.

Carpal tunnel syndrome

Carpal tunnel syndrome is the most common entrapment mononeuropathy. It is
caused by compression of the median nerve as it passes through the fibro-osseous
tunnel beneath the flexor retinaculum. The carpal tunnel may be narrowed by arthritic
changes in the wrist joint, particularly rheumatoid arthritis; soft tissue thickening as may occur in myxoedema and acromegaly; and may also be associated with oedema, obesity or pregnancy. Usually the condition is idiopathic. Normally the median nerve slides smoothly in and out of the carpal tunnel during flexion and extension of the wrist: when the nerve is compressed, additional damage may be produced during these movements. The dominant hand is usually affected first, probably because this hand is used more frequently and more vigorously. Typically, the syndrome produces pain, paraesthesia and numbness in the thumb, index, middle and medial side of the ring finger, which is worse at night and on gripping objects. The palmar branch of the median nerve is spared since it does not pass through the carpal tunnel. With time, the compression leads to wasting and weakness of abductor pollicis brevis. Treatment is usually surgical decompression of the nerve by dividing the flexor retinaculum.

**Median nerve division at the wrist**

The median nerve is vulnerable to division from lacerations at the wrist. Division leads to paralysis of the lumbricals to the index and middle fingers and the thenar muscles (apart from flexor pollicis brevis and adductor pollicis), as well as loss of sensation to the thumb, index, middle and radial half of the ring fingers. The radial half of the hand becomes flattened as a result of wasting of the thenar muscles and the adducted posture of the thumb.

**Ulnar nerve**

At the wrist, the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) with the ulnar artery, and divides into superficial and deep terminal branches.

**Dorsal branch**

The dorsal branch arises approximately 5 cm proximal to the wrist. It passes distally and dorsally, deep to flexor carpi ulnaris, perforates the deep fascia, descends along the medial side of the back of the wrist and hand and then divides into two, or often three, dorsal digital nerves. The first supplies the medial side of the little finger, the second, the adjacent sides of the little and ring fingers, while the third, when present, supplies adjoining sides of the ring and middle fingers. The latter may be replaced, wholly or partially, by a branch of the radial nerve, which always communicates with it on the dorsum of the hand (Fig. 50.45A). In the little finger, the dorsal digital nerves extend only to the base of the distal phalanx, and in the ring finger they extend only to the base of the middle phalanx. The most distal parts of the little finger and of the ulnar side of the ring finger are supplied by dorsal branches of the proper palmar digital branches of the ulnar nerve. The most distal part of the lateral side of the ring finger is supplied by dorsal branches of the proper palmar digital branch of the median nerve.

**Superficial and deep terminal branches**

**Superficial terminal branch**

The superficial terminal branch supplies palmaris brevis and the medial palmar skin. It divides into two palmar digital nerves, which can be palpated against the hook of the hamate bone. One supplies the medial side of the little finger, the other (a common
palmar digital nerve) sends a twig to the median nerve and divides into two proper
digital nerves to supply the adjoining sides of little and ring fingers. The proper digital
branches are distributed like those derived from the median nerve.

**Deep terminal branch**

The deep terminal branch accompanies the deep branch of the ulnar artery as it
passes between abductor digiti minimi and flexor digiti minimi and then perforates
opponens digitii minimi to follow the deep palmar arch dorsal to the flexor tendons (Fig.
50.46). At its origin it supplies the three short muscles of the little finger. As it crosses
the hand, it supplies the interossei and the third and fourth lumbricals. It ends by
supplying adductor pollicis, the first palmar interosseous and usually flexor pollicis
brevis. It sends articular filaments to the wrist joint.

![Fig. 50.46 Deep structures in the left palm and wrist showing the deep branch of the ulnar nerve.](image.png)

The medial part of flexor digitorum profundus is supplied by the ulnar nerve, as are the
third and fourth lumbricals which are connected with the tendons of this part of the
muscle. Similarly, the lateral part of flexor digitorum profundus and the first and
second lumbricals are supplied by the median nerve. The third lumbrical is often
supplied by both nerves. The deep terminal branch is said to give branches to some intercarpal, carpometacarpal and intermetacarpal joints: precise details are uncertain. Vasomotor branches, arising in the forearm and hand, supply the ulnar and palmar arteries.

**Ulnar tunnel syndrome**

Ulnar tunnel syndrome is an entrapment neuropathy of the ulnar nerve as it passes through Guyon's canal at the wrist. Causes of compression at this site include a ganglion, trauma, and proximity of aberrant or accessory muscles. The symptoms include pain in the hand or forearm and sensory changes in the palmar aspect of the little and ulnar half of the ring fingers, however sensation on the ulnar aspect of the dorsum of the hand is normal. In addition there may be weakness and wasting of the intrinsic muscles of the hand supplied by the ulnar nerve, with clawing posture in extreme cases.

Surgical treatment involves decompression of the nerve by division of the roof of Guyon's canal and removal of the causative lesion, e.g. ganglion.

**Ulnar nerve division at the wrist**

Division of the ulnar nerve at the wrist paralyses all the intrinsic muscles of the hand (apart from the radial two lumbricals). The intrinsic muscle action of flexing the metacarpophalangeal joint and extending the interphalangeal joints is therefore lost. The unopposed action of the long extensors and flexors of the fingers cause the hand to assume a clawed appearance with extension of the metacarpophalangeal joints and flexion of the interphalangeal joints. The clawing is less intense in the index and middle fingers because of their intact lumbricals, supplied by the median nerve. (For a detailed account of the hand posture adopted in ulnar nerve lesions, see Smith 2002.)

There is sensory loss over the little finger and the ulnar half of the ring finger. In comparison to an ulnar nerve division at the elbow, the skin over the ulnar aspect of the dorsum of the hand is spared because the dorsal branch of the ulnar nerve is given off approximately 5 cm proximal to the wrist joint.

A combined median and ulnar nerve palsy at the wrist results in a full claw hand with thenar and hypothenar flattening, and thumb adduction and flexion. This posture is known as a simian hand because of the similarity to the appearance of the hand of an ape.

**Radial nerve**

Branches of the superficial branch of the radial nerve reach the hand by curving around the wrist over the tendons of abductor pollicis longus and extensor pollicis brevis. They divide into dorsal digital nerves. On the dorsum of the hand they usually communicate with the posterior and lateral cutaneous nerves of the forearm.

**Dorsal digital nerves**

There are usually four or five small dorsal digital nerves. The first supplies the skin of the radial side of the thumb and the adjoining thenar eminence, and communicates with branches of the lateral cutaneous nerve of the forearm. The second supplies the
medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers; the fifth communicates with a ramus of the dorsal branch of the ulnar nerve and supplies the adjoining sides of the middle and ring fingers, but is frequently replaced by the dorsal branch of the ulnar nerve. The pollicial digital nerves reach only to the root of the nail, those in the index finger, midway along the middle phalanx, those to the middle and the lateral part of the ring finger may reach no further than the proximal interphalangeal joints. The remaining distal dorsal areas of the skin in these digits are supplied by palmar digital branches of the median and ulnar nerves. The superficial terminal branch of the radial nerve may supply the whole dorsum of the hand.

*In particular the following chapters in this book: Garcia-Elias M, Anatomy of the wrist; and Ryu J, Biomechanics of the wrist.*
Development of the limbs depends on a series of complex cell–cell interactions that have been identified in experiments on amphibian, avian and reptilian species; the range demonstrates the remarkable conservation of developmental processes. Fate maps have revealed which structures in the limb arise from particular cells or groups of cells in the embryo and considerable progress has been made in identifying the genetic basis of limb development. The finding that the same molecules are involved in developing embryos of both model organisms and humans has promoted an increasing convergence between developmental biology and clinical genetics.

The limbs develop from somatopleuric mesenchyme in the lateral body wall. Regions of the somatopleuric mesenchyme at specific positions along the main body axis proliferate extensively to give rise to limb buds. These buds are the first visible signs of limb development and are rimmed by a longitudinal ridge of high columnar epithelial cells, the apical ectodermal ridge (Fig. 51.1).

The early limb bud contains a mixed population of mesenchymal cells: somatopleuric mesenchyme gives rise to the connective tissues of the limb, including cartilage, bone, tendon and loose connective tissue, paraxial mesenchyme from the somites gives rise to the myogenic cells of the muscles, and angiogenic mesenchyme produces an extensive vascular network in the early limb bud. Motor and sensory nerves and the neural crest derived Schwann cells and melanocytes of the skin, migrate into the developing limb somewhat later.
Fig. 51.1 Scanning electron micrographs to show the development of the upper limb. A, An early limb bud viewed from the postaxial border. B, Limb bud viewed from postaxial border; the apical ectodermal ridge (arrowed) can be seen. C, Limb bud, dorsolateral view; the shoulder and elbow region can be discerned, and a hand plate has formed. The apical ectodermal ridge is still obvious at the margin of the hand plate. D, Digital rays are present in the hand plate and the margin of the plate is becoming notched. E, The fingers are nearly separated and proliferation is commencing at the distal end of each digit to form the nail bed. F, The fingers each have tactile pads distally, and nail development continues.

AXES OF LIMBS

For descriptive, experimental and conceptual purposes, it has been necessary to define and name various 'axes', borders, surfaces and lines in relation to the developing limb bud (Fig. 51.2). An imaginary line from the centre of the elliptical base of the bud, through the centre of its mesenchymal core, to the centre of the apical ectodermal ridge, defines the proximodistal axis of the limb bud (previously known in descriptive embryology simply as the axis). Named in relation to the latter, the cranially placed limb border is the preaxial border, and the caudally placed limb border is the postaxial border. (In tetrapods and birds, the last two are termed anterior and posterior borders, respectively.) Any line that passes through the limb bud from preaxial to postaxial border, orthogonal to the proximodistal axis, constitutes a craniocaudal axis. The dorsal and ventral ectodermal surfaces thus clothe their respective aspects from preaxial to postaxial borders, and any line that passes from dorsal to ventral aspect, orthogonal to both proximodistal and craniocaudal axes, constitutes a dorsoventral axis. It should be noted here that the terms dorsal and ventral axial lines are to be used exclusively in relation to developing and definitive patterns of cutaneous innervation of the limbs and their associated levels of the trunk.
Fig. 51.2. Axes of the developing limb and specification of structures along the different axes. A, Proximodistal; B, craniocaudal; limb bud (approximately stage 14) viewed from dorsal side; C, dorsoventral; limb bud viewed from distal end. The pattern of development of limb structures and the ectodermal specializations are controlled by the limb mesenchyme. Outgrowth of limb development is controlled by the apical ectodermal ridge and this is accompanied by the laying down of structures along the proximodistal axis; craniocaudal pattern is controlled by zone of polarizing activity (polarizing region); dorsoventral pattern is controlled by signals from dorsal and ventral ectoderm, shown in cross section, section taken in plane shown by dotted line.

The three developmental axes (proximodistal, craniocaudal, and dorsoventral) can be identified in the developing limb bud by stage 13. Experiments in chick embryos have shown that development of structures in relation to each of these three principal axes seem to be specified by different mechanisms (Fig. 51.2). Outgrowth along the proximodistal axis is controlled by the apical ectodermal ridge and subjacent somatopleuric mesenchyme; outgrowth of the limb bud is accompanied by the sequential formation of limb structures along the proximodistal axis. The craniocaudal axis is controlled by a small population of mesenchymal cells on the postaxial border of the limb bud; this region of mesenchyme is termed the zone of polarizing activity or polarizing region. The dorsoventral axis of the limb appears to be controlled by the surface ectodermal covering of the limb bud.

Early differential growth of parts of the limb bud results in two main changes to the originally symmetrical axes of the limb. The dorsal aspect of the limb grows faster than the ventral, which causes the limb bud to curve around the body wall. The ventral surface of the limb (closest to the body wall) remains relatively flat, but the dorsal surface bulges into the amniotic cavity. The originally laterally facing apical ectodermal ridge becomes increasingly directed ventrally.

**APICAL ECTODERMAL RIDGE**

The outgrowth of a limb bud is controlled by the apical ectodermal ridge. For many years it was thought that a timing mechanism that specified proximodistal pattern operated in the zone of proliferating undifferentiated mesenchyme cells at the tip of a developing limb bud. This zone was therefore called the progress zone. It was
assumed that as cells left the progress zone their proximal distal value became fixed. Cells that spent a short time at the tip of the limb bud would form proximal structures, while cells that spent a longer time at the tip of the limb bud would form distal structures. However, it has been suggested more recently that proximodistal pattern is specified in the very early limb bud and that structures are elaborated as the bud grows out.

The fundamental epithelial–mesenchymal interactions seen in limb development are discussed in detail in Hinchcliffe & Johnson (1980) and the more recently discovered genetic basis of these interactions in Ferretti & Tickle (2006). The knowledge of limb embryology gained from studying chicks may be summarized as follows (Fig. 51.3). The apical ectodermal ridge provides the orientating influence for limb bud outgrowth. Its removal results in cessation of limb development, whereas grafting a second apical ectodermal ridge results in two axes of development, and duplication of distal structures (Fig. 51.3). There is evidence that the limb mesenchyme beneath the apical ectodermal ridge provides an apical ectodermal ridge maintenance factor that is essential to the function of the ridge. Thus, when leg bud cells are grafted to the tip of a wing bud beneath the apical ectodermal ridge, the ridge is maintained and bud outgrowth continues (it should be noted that the leg cells, even though placed in a wing bud, still form distal leg structures) (Fig. 51.3). In addition, the leg mesenchyme will pass information to the local ectoderm eliciting the appropriate epidermal development, which in this case is the formation of scales rather than feathers.
Fig. 51.3 A–C. Experimental manipulations that identified fundamental interactions involved in patterning the three main axes of the limb in the chick.
ZONE OF POLARIZING ACTIVITY

The zone of polarizing activity is a small region of somatopleuric mesenchyme on the postaxial border of the limb. When a second zone of polarizing activity is grafted beneath or adjacent to the apical ectodermal ridge at the preaxial border of a chick wing bud, duplication of distal limb structures occurs, generating a mirror-image pattern of six digits (Fig. 51.3). The digit closest to the zone of polarizing activity is always the most postaxial digit (in the chick wing this is digit 4), while more preaxial digits develop further away from the zone of polarizing activity. Thus signalling from the zone of polarizing activity appears to control both digit number and digit pattern. It has been suggested that digit number is controlled by regulation of the production of the apical ectodermal ridge maintenance factor, while digit pattern is regulated by production of a diffusible morphogen that acts in a concentration dependent fashion.
ECTODERMAL INTERACTION

It is possible to remove the mesenchymal core of an early chick limb bud leaving the surface ectodermal epithelium. When the ectodermal epithelium from a left limb bud is recombined with the mesenchymal core from a right limb bud, keeping the cranio-caudal axis in register, the distal part of the limb that subsequently develops conforms to the polarity of the ectoderm rather than that of the mesenchyme (Fig. 51.3). This can be seen in the pattern of muscles, orientation of the joints and eventual characteristic differentiation of the epidermis. Thus signals from the ectoderm control the pattern along the dorso-ventral axis.
MOLECULAR BASIS OF CELL–CELL INTERACTIONS

The apical ectodermal ridge secretes fibroblast growth factors that act on the underlying mesenchyme and maintain the zone of polarizing activity. The latter expresses Sonic hedgehog (Shh), a gene encoding another class of secreted protein that mediates cell–cell signalling. Sonic Hedgehog protein acts on adjacent mesenchyme cells and maintains the expression of the gene encoding Gremlin (an extracellular bone morphogenetic protein antagonist), which functions as an apical ectodermal ridge maintenance factor. Sonic hedgehog also plays a pivotal role in digit patterning: it diffuses across the limb bud and responding cells transduce the signal through the Gli family of transcription factors. (The Gli proteins are bifunctional effectors of Shh signalling and can lead to either activation or repression of expression of gene targets.) Dorsal limb ectoderm expresses Wnt7a, which acts as a dorsalizing signal.

Among the genes expressed in response to these cell–cell signalling molecules are 5′ members of two Hox gene complexes. Hox-d gene expression in the distal limb bud shows a nested arrangement similar to that of Russian dolls: the postaxial border of the limb bud tip expresses five Hox-d genes (d-13, d-12, d-11, d-10 and d-9), while in the next preaxial portion only four genes are expressed (d-12, d-11, d-10 and d-9), this sequential loss of expression of Hox-d genes is repeated until only d-9 is expressed in the most preaxial regions of the limb bud. The fact that five different Hoxd expression domains can be distinguished has prompted the suggestion that this may be why we have five fingers (and toes), but the explanation is unlikely to be so simple.
SKELETAL ELEMENTS OF THE LIMB

It has been suggested that formation of the cartilaginous elements of a limb is related to the shape of the limb and the conditions necessary for chondrogenesis. An antichondrogenic zone beneath the ectoderm of a developing limb prevents chondrogenesis within the dermis and myogenic zones. Foci of chondrogenesis occur in the centre of the limb bud where cell density is greatest. One centre of chondrogenesis forms in the proximal region of an early limb bud. As the limb bud lengthens it also widens, forming next two centres of chondrogenesis and five centres that appear further distally. The Sox9 transcription factor is essential for chondrocyte differentiation: expression of the Sox9 gene is coincident with expression of the gene that encodes collagen type II, the collagen characteristic of cartilage extracellular matrix. Sox9 gene transcripts are expressed in the humeral and forearm skeletal elements of human embryos at approximately 44 days, and in carpals, metacarpals and phalanges, in addition to more proximal elements, at approximately 52 days (Fig. 51.4).
**Fig. 51.4** Sox9 expression in the skeleton of developing limbs of human embryos. **A**, Stage 18; approximately 44 days postovulation. 1. Humerus. 2. Ribs. 3. Heart. 4. Forearm. 5. Vertebral body. 6. Scapula. **B**, Stage 21; approximately 52 days postovulation. 1. Carpal bone. 2. Metacarpal bone. 3. Phalanges. 4. Humerus. 5. Scapula. 6. Rib. Sox9 transcripts detected in sections with radioactively labelled probes followed by autoradiography, positive signal represented by silver grains that show up as white areas. Scale bars represent 500 µm in both **A** and **B**.

*(The human tissue was provided by the joint MRC-Wellcome Human Developmental Biology Resource (http://www.hdbr.org) at the Institute of Human Genetics, Newcastle upon Tyne, UK. By courtesy of Dr Susan Lindsay, Institute of Human Genetics, University of Newcastle upon Tyne, UK.)*
The apical ectodermal ridge controls the width of the digital plate, and the number of digits that develop is related to the width of the limb bud. Zones of preprogrammed cell death can be identified on the preaxial and postaxial borders of the limb which limit the length of the apical ectodermal ridge. (It should be noted that in the literature relating to work on animal embryos, pre- and post-axial borders are termed anterior and posterior borders respectively, and therefore the regions in which programmed cell death occurs are termed the anterior and posterior necrotic zones.) If the length of the apical ectodermal ridge is reduced, fewer digits will form (oligodactyly), whereas if the apical ectodermal ridge becomes longer, more digits will form (polydactyly). Supernumerary digits may develop on either the pre- or postaxial borders. Other regions of apoptotic cell death occur between the digits and result in digital separation, but these appear later than the anterior and posterior necrotic zones: the resultant debris in all of the necrotic zones is removed by macrophages.

The first evidence of bone formation is seen at the mid section of the diaphyses of long bones at 7–8 weeks in human embryos. Vascular invasion of the cartilage matrix precedes the formation of a periostial collar, and subsequently extends proximally and distally until it reaches the future epiphysial level, where a growth plate will be established. By 10 weeks, columns of chondrocytes can be seen at the epiphysial level of most bones. However, only the lower end of the femur and upper end of the tibia develop secondary ossification centres before birth.

For further details describing the development of cartilage see page 81, and the development of bone see page 92. For further details about the development of specific limb bones see the appropriate regional chapter.

**DEVELOPMENT OF JOINTS**

Regions of developing cartilage are easily recognized histologically in the developing limb because they consist of widely spaced cells surrounded by matrix. Somatopleuric mesenchymal cells are more condensed between the developing skeletal elements, and form plates of interzonal mesenchyme which mark the sites of future joints. Their subsequent development varies according to the type of joint that is formed.

In fibrous joints, the interzone is converted into collagen, which is the definitive medium connecting the bones involved. In synchondroses it becomes (growth) cartilage of the modified hyaline type, and in symphyses it is predominantly fibrocartilage. The interzonal mesenchyme of developing synovial joints becomes trilaminar when a more tenuous intermediate zone appears splitting the mesenchyme into two dense strata. As the skeletal
elements chondrify, and in part ossify, the dense strata of the interzonal mesenchyme also become cartilaginous; subsequent cavitation of the intermediate zone establishes the cavity of the joint. The loose mesenchyme around the cavity forms the synovial membrane and probably also gives rise to all other intra-articular structures, such as tendons, ligaments, discs and menisci. In joints containing discs or menisci, and in compound articulations, more than one cavity may appear initially, sometimes merging later into a complex single cavity. As development proceeds, thickenings in the fibrous capsule can be recognized as the specializations peculiar to a particular joint. (In some joints, such accessions to the fibrous capsule are derived from neighbouring tendons, muscles or cartilaginous elements.) Although the initial stages in the process of cavitation of joints is independent of movements, a true joint cavity can form only in the presence of movements (Pitsillides 2006). The literature suggests that all musculoskeletal elements are in their appropriate positions by 10 weeks. For detailed accounts of the process, consult O’Rahilly & Gardner (1975) and Uhthoff (1990).

Musculature of the limb

It is now well established that all limb myogenic precursor cells originate from the somites. These cells are committed at an early stage and can be identified in the lateral halves of the somites. After the mesenchymal sclerotome cells have migrated from the epithelial somite, the remaining dorsolateral portion is termed the epithelial plate or dermomyotome of the somite (Fig. 44.3). Cells from the dorsomedial edge of the dermomyotomes form the axial musculature, whereas at limb levels cells de-epithelialize and migrate from the ventrolateral edges of the dermomyotome into the limb bud. These precursor limb myoblasts migrate through a non-random, structured network of extracellular fibrils. At their leading ends the migrating cells exhibit filopodia which are in contact with the extracellular fibrils or with other cells: it is believed that the orientation of the extracellular fibrils may direct the migration of the cells. The precursor muscle cells do not differentiate into muscle before their migration into the limb, probably in response to inhibitory signals produced by the somatopleuric mesenchyme.

The myogenic cells colonize the limb bud in a proximodistal direction, but never reach the most distal portion of the limb, where there seems to be a distal boundary for the muscle cells. Myogenic cells are still indifferent regarding their region-specific determination when they first enter the limb. When brachial or pelvic level somites are grafted opposite the leg-forming region instead of the wing, or opposite the wing instead of the leg, the precursor cells will give rise to normal leg or wing musculature respectively, i.e. the muscle cells, unlike the somatopleuric mesenchyme, have no ‘limbness’. Further, the muscle pattern developed in the limb reflects the pattern of the skeletal elements: duplication or lack of digits is accompanied by the duplication or lack of the corresponding muscles.
Two subpopulations of myogenic cells can be discerned in the limb bud. In the early buds, there are mainly replicating presumptive myoblasts, considered to be premitotic, whereas in later stages there are also postmitotic myoblasts. It is interesting that the invading myoblasts are still replicating; this may be a prerequisite for the formation of the considerable amount of skeletal muscular tissue that will develop in the limbs.

The first myogenic cells to arrive in the limb form the principal dorsal and ventral premuscle masses. It is believed that all classes of tetrapods begin limb muscle development with these blocks, which produce all the skeletal muscle in the limb. The blocks of premuscle undergo a spatiotemporal sequence of divisions and subdivisions as the limb lengthens, and this leads to the individualization of about 19 muscles in the upper limb and 14 muscles in the lower limb. The mechanisms that create gaps that lead to these divisions of the muscle masses are not known. In the upper limb, the premuscle masses first divide into three masses, the next division gives rise to the muscles attached to the carpus, and the final division produces the long muscles of the digits. A similar pattern is seen in the lower limb. Thus the patterning of the musculature of the limb is controlled by the somatopleuric mesenchyme.

Each anatomical muscle appears as a composite structure. The muscle cells and myosatellite cells are of somitic origin, and the connective tissue envelopes and the tendons are of somatopleuric origin. The precise way in which the muscles become anchored to the developing bones by the tendons is not clear.

For further development of skeletal muscle, see page 115.
EMBRYONIC MOVEMENTS

Embryonic movements are vital for development of the musculoskeletal system (reviewed by Pitsillides, 2006). They have effects on the developing muscle, and are necessary to align trabeculae within bones, and to ensure the correct attachments of the tendons and the appropriate coiling of the constituent collagen fibres within the tendons. Simple movements of an extremity have been observed sporadically as early as the seventh week of gestation. Combined movements of limb, trunk and head commence between 12 and 16 weeks of gestation in human embryos. Movements of the embryo and fetus encourage normal skin growth and flexibility, in addition to the progressive maturation of the musculoskeletal system.
FETAL MOVEMENTS

Fetal movements have been detected by ultrasonography in the second month of gestation. Those related to trunk and lower limb movements are perceived consistently by the mother from about 16 weeks' gestation (quickening). Movements of the fetus often involve slow and asymmetric twisting and stretching movements of the trunk and limbs which resemble athetoid movements. There may also be rapid, repetitive, wide-amplitude limb movements, similar to myoclonus.

By 32 weeks' gestation, symmetric flexor movements are most frequent. By term, the quality of the movements has generally matured to smooth alternating movement of the limbs, with medium speed and intensity. The reduced effect of gravity in utero may cause certain fetal movements to appear, on ultrasonography, more fluent than the equivalent movements observed postnatally. The number of spontaneous movements decreases after the 35th week of gestation, and from this time there is an increase in the duration of fixed postures. This restriction of normal fetal movements in late gestation reflects the degree of compliance of the maternal uterus: there is a slowing of growth at this time.

In addition to promoting normal musculoskeletal development, movements of the fetus encourage skin growth and flexibility indirectly. Fetuses with in utero muscular dystrophies, or other conditions that result in small or atrophied muscles, have webs of skin, pterygia, which pass across the flexor aspect of the joints and severely limit movement. Multiple pterygium syndrome is characterized by webbing across the neck, the axillae and antecubital fossae. Usually, the legs are maintained straight and webbing is not seen at the hip and knee. A group of congenital disorders, collectively termed ‘multiple congenital contractures’, may result from genetic causes, or limitations of embryonic and fetal joint mobility, or may be secondary to muscular, connective tissue, skeletal or neurological abnormalities. These conditions may be recognized on prenatal ultrasound examination by the appearance of fixed, immobile limbs in bizarre positions, or by webbing in limb flexures. Specific syndromes, lethal multiple pterygium syndrome, and congenital muscular dystrophy, have been described.

The workload undertaken by the musculoskeletal system before birth is relatively light because the fetus is supported by the amniotic fluid and therefore under essentially weightless conditions. The load on the muscles and bones is generated by the fetus itself, with little gravitational effect. The reduction of gravitational force afforded by the supporting fluid means that all parts of the fetus are subject to relatively equal forces, and that the position assumed by the fetus relative to gravity is of little consequence. This is important to ensure the normal modelling of fetal bones, especially the skull. Skulls of premature babies may become distorted as a result of the weight of
the head on the mattress, despite regular changes in position, and the application of oxygen therapy via a mask attached by a band around the head can cause dysostosis of the occipital bone.
VASCULATURE OF THE LIMB

ARTERIES

The early limb bud receives blood via intersegmental arteries that contribute to a primitive capillary plexus. At the tip of the limb bud, there is a terminal plexus which is constantly renewed in a distal direction as the limb grows (see Figs 52.1, 85.1). Later, one main vessel, the axial artery, supplies the limb and the terminal plexus.

The development of the vasculature in the limb precedes the morphological and molecular changes that occur within the limb mesenchyme. The differentiation of cartilage within the limb occurs only after local vascular regression begins, and only in areas with few or no capillaries. Regions of mesenchyme free of capillaries and at high cell density are the sites of chondrogenesis. It is not known whether the presence, or lack, of blood vessels affords different local environmental stimuli for mesenchymal cells (by varying the supply of nutrients to the tissue), or whether the local environment is controlled by the endothelial cells. Similarly, it is not clear whether inductive factors from the limb mesenchyme cause the changes that occur in the pattern of blood vessels.
VEINS

At the tip of the early limb bud, blood in the terminal capillary plexus returns to the body via a marginal vein that develops along the pre- and postaxial borders of the limb. As the limb enlarges, the marginal vein can be subdivided into pre- and postaxial veins, which run along their respective borders and which are the precursors of the superficial veins of the limb. Generally, the preaxial (superficial) veins join the deep veins at the proximal joint, and the postaxial (superficial) veins join the deep veins at the distal joint of the limb. Deep veins develop *in situ* alongside the arteries.

STAGES OF UPPER LIMB DEVELOPMENT

The upper limb bud is first visible as a ridge along the lateral longitudinal axis of the body wall opposite somites 8–10, at the level of the entrance to the cranial intestinal portal during stage 12. It enlarges, protruding laterally from its elliptical base at the body wall as a flattened plate, with a curved border and an apical ectodermal ridge forming its distal tip. It also has initially equal and relatively flat dorsal and ventral ectodermal surfaces, and a somatopleuric mesenchymal core.

By stage 13 the upper limb bud is curved ventrally. In stage 14 the bud has elongated and the preaxial border has started to lengthen. At this stage the limb bud is opposite the developing ventricles of the heart. In stage 15, the upper limb can be subdivided into definite regions. The proximal portion of the limb which still shows the dorsal bulge and ventral curve is the shoulder and upper arm region; the next distal portion (which was derived from the increase in the length of the preaxial border) can now be identified as the forearm; the most distal portion is now expanded into a flattened hand plate.

At stage 16, the upper limb appears much more substantial. It is sometimes close to the body wall and sometimes abducted. The hand plate has the first indications of digit rays. By stage 17, the upper limb has an elbow region and digit rays; in advanced members of this stage, the hand plate has a crenated rim indicating the beginning of tissue removal between the digits (see Fig. 51.1). In stage 18 embryos (44 days), there is further crenation of the hand plate between the digit rays. Changes during stages 19–23 are concerned with growth of the limb and separation of the digits. The hands now curve over the cardiac region. The distal phalangeal portions of the fingers enlarge at stage 21, forming the nail beds.

Most of the bones in the appendicular skeleton are derived from somatopleuric mesenchyme. Within the upper limb although the clavicle and coracoid portion of the scapula arise from somatopleuric mesenchyme, the body and spine of the scapula are derived from the somites. Prechondroblasts are present in the upper limb at stage 13, and condensations of cartilage can be detected at stage 16, when the humeral anlage can be recognized. Cavitation of the shoulder and elbow joints occurs at 7–8 weeks. By stage 17, when the radius and ulna chondrify, the branched tips of the radial, median and ulnar nerves have migrated to the distal hand plate. The carpal bones chondrify at stage 18, when the hand plate shows notching of the digital rays.

VESSELS IN THE UPPER LIMB

In the upper limb, usually only one arterial trunk, the subclavian, persists; it probably represents the lateral branch of the seventh intersegmental artery. Its main continuation (axis artery) to the upper limb (Fig. 52.1), later the axillary and brachial arteries, passes into the forearm deep to the flexor muscle mass and terminates as a deep plexus in the developing hand. The original axial vessel ultimately persists as the anterior interosseous artery and the deep palmar arch. A branch from the main trunk passes dorsally between the early radius and ulna as the posterior interosseous artery; a second branch accompanies the median nerve into the hand, where it ends in a superficial capillary plexus. The radial and ulnar arteries are the latest arteries to
appear in the forearm. Initially the radial artery arises more proximally than the ulnar artery, crosses in front of the median nerve, and supplies biceps. Later, the radial artery establishes a new connection with the main trunk at or near the level of origin of the ulnar artery and the upper portion of its original stem usually disappears. On reaching the hand, the ulnar artery links up with the superficial palmar plexus, from which the superficial palmar arch is derived, while the median artery commonly loses its distal connections and is reduced to a small vessel. The radial artery passes to the dorsal surface of the hand; after giving off dorsal digital branches, it traverses the first intermetacarpal space and joins the deep palmar arch.
For a number of reasons, anomalies of the forelimb arterial tree are fairly common. These arteries have multiple and plexiform sources; display a temporal succession of the emergence of principal arteries, anastomoses and periarticular networks; and some paths that are initially functionally dominant subsequently regress. In general, anomalous patterns may present as differences in the mode and proximodistal level of branching; the presence of unusual compound arterial segments; aberrant vessels that connect with other principal vessels, arcades or plexuses; vessels that occupy exceptional tissue planes (e.g. superficial fascia instead of the usual subfascial route), or which have unexpected neural, myological or osteoligamentous relationships.

In the upper limb, the preaxial vein becomes the cephalic vein, and drains into the axillary vein at the shoulder. The postaxial vein becomes the basilic vein, which passes deep in the arm to continue as the axillary vein.
NEONATAL UPPER LIMB

In general, the upper limbs in the neonate are proportionately shorter than they are in the adult. They are long compared with the neonatal trunk and lower limbs, and extend to the upper thigh as they do in the adult, but the trunk is much shorter in the neonate (see Fig. 14.6). At birth, the upper limbs are about the same length as the lower limbs, but much more developed. When the proportions of parts of the upper limb are examined, the forearm is longer than the upper arm in the newborn, more so in boys than girls. Only primary centres of ossification are present in the upper limb, apart from a centre in the head of the humerus. The elbow of the newborn cannot achieve full extension, being some 10–15% short; it can flex to 145°. The neonate has a relatively strong grasp within the first few days. The fingernails of the upper limb usually extend to the finger tips or just beyond. They are soft at birth but soon dry and become quite firm and sharp.

PERIPHERAL ARTERIAL PUNCTURE IN THE NEONATE

It is common practice to insert a small-bore cannula into a peripheral artery in neonates receiving intensive care when either the umbilical artery is not accessible or there are clinical reasons to avoid cannulation of the umbilical vessels. Transillumination can be used to provide an outline of the artery to be cannulated. The peripheral arteries that are most commonly used are the radial artery, just above the anterior surface of the wrist and the posterior tibial artery, posterior to the medial malleolus. The proximity of the ulnar nerve to the ulnar artery increases the risk of nerve damage associated with arterial cannulation of the ulnar artery, and the relatively poor collateral circulation associated with the dorsalis pedis artery means that this artery is used only as a last resort. The brachial artery at the antecubital fossa also has a poor collateral circulation and the median nerve is in close proximity; it is generally considered, therefore, that cannulation of this artery is not justified.

Confirmation that an adequate collateral circulation is present when cannulating the radial artery can be obtained by performing Allen's test, in which both the radial and ulnar arteries are compressed at the wrist after exsanguination of the hand; release of pressure on the ulnar artery while maintaining occlusion of the radial artery should result in reperfusion of the hand if an adequate collateral ulnar arterial supply is present. Alternatively, intact arterial flow can usually be confirmed, particularly in the preterm infant, by direct visualization of the arteries using transillumination. A cold light source is placed on the posterior aspect of the lower forearm and the shadow of the pulsating arteries can be seen on the anterior surface of the forearm.
UPPER LIMB ANOMALIES

Approximately 1 in 600 neonates will have a congenital anomaly of the hand or forearm, 30% of which will be bilateral, and will occur with an approximately equal frequency in males and females. A defect is twice as likely to occur in the upper limb than in the lower limb.

A classification of congenital limb malformation uses seven subgroups (Swanson 1976). These describe a clinical picture and do not always relate accurately to the developmental process occurring in the limb. Failure of formation of parts of a limb is caused by developmental arrest affecting the long bones. The second subgroup, failure of differentiation, includes unsuccessful separation of parts, and so includes the range of syndactylies. Groups three to five include limb duplication, overgrowth and undergrowth. Group six includes limb amputations, mainly by adherent amniotic bands, and the last group includes all other generalized skeletal anomalies.

LIMB REDUCTION DEFECTS

Limb reduction defects are categorized as failures of development. The basis of limb reductions seen in infants whose mothers took thalidomide during their pregnancy seems likely to be due to death of mesenchyme cells in the early limb bud causing phocomelia. Proximal segments of the limb were lost although, in some cases, normal distal segments still formed. Similar defects can be produced by X-irradiation of chick embryo limb buds and there is now evidence that thalidomide interferes with vascularization and this could lead to cell death. In congenital absence of the radius, the ulna is usually shortened and curved towards the radial side. If the thumb is present, it is usually hypoplastic and the first metacarpal is absent.

Inheritance of autosomal dominant genes may cause anomalies of the hand. This could, for example, result in absence of the central digit ray of the distal hand plate and subsequent absence of the middle or ring finger and its metacarpals. Extra digits, preaxially, could result from ectopic polarizing activity due to mutations in regulatory regions that control expression of the Shh gene specifically in the developing limb bud. Other changes in digit number may be the result of alterations in limb bud width and the length of the apical ectodermal ridge.
ANOMALIES OF THE DIGITS

Webbing of the fingers is the most common congenital anomaly of the hand. It occurs because of failure to remove cells between the digit rays during stages 19–23, or because of a dominantly inherited disorder.

Clinodactyly is a congenital condition in which the little finger is curved towards the ring finger. It can occur in isolation, or in association with chromosomal abnormalities like Down's syndrome. Camptodactyly is a congenital condition in which the little finger, and sometimes the ring finger, is held in a fixed flexed position. Symphalangism is a rare congenital disorder in which there is fusion of the interphalangeal joints. The affected finger is stiff, skin creases are absent over the affected joint, there is minimal joint space, and sometimes the digit is shorter than normal. Several different types of brachydactyly, shortening of the digits, can be recognized according to which digits and which parts of these digits are affected. The genetic basis of four different types of brachydactyly has now been determined, which is particularly gratifying because brachydactyly was the first condition in humans to be recognized as a dominant Mendelian condition.
REFERENCES

The thorax is the upper part of the trunk. It consists of an external musculoskeletal cage, the thoracic wall, and an internal cavity that contains the heart, lungs, oesophagus, trachea, thymus, the vagus and phrenic nerves and the right and left sympathetic trunks, the thoracic duct and major systemic and pulmonary blood vessels. Inferiorly the thorax is separated from the abdominal cavity by the diaphragm, superiorly it communicates with the neck and the upper limbs. The thoracic wall also offers protection to some of the abdominal viscera: the greater part of the liver lies under the right dome of the diaphragm; the stomach and spleen lie under the left dome of the diaphragm; the posterior aspects of the superior poles of the kidneys lie on the diaphragm and are anterior to the twelfth rib on the right, and to the eleventh and twelfth ribs on the left (Fig. 53.1).

Variations in thoracic dimensions and proportions are partly individual and also linked to age, sex and race. At birth, the transverse diameter is relatively less than it is in the adult, but adult proportions develop as walking begins. Thoracic capacity is less in females than it is in males, both absolutely and proportionately: the female sternum is shorter, the thoracic inlet more oblique, and the suprasternal notch is level with the third thoracic vertebra (whereas it is level with the second in males). In all individuals, the size of the thoracic cavity changes continuously, according to the movements of the ribs and diaphragm during respiration (see Ch. 58), and the degree of distension of the abdominal viscera.
MUSCULOSKELETAL FRAMEWORK

BONES AND JOINTS

The thoracic skeleton consists of twelve thoracic vertebrae and their intervening intervertebral discs (midline, posterior), twelve pairs of ribs and...
their costal cartilages (predominantly lateral) and the sternum (midline, anterior). When articulated, they form an irregularly shaped osteocartilaginous cylinder, reniform in horizontal section, which is narrow above, broad below, flattened anteroposteriorly and longer behind (see Fig. 54.7). Laterally the thoracic cage is convex and is formed by the ribs, and anteriorly it is slightly convex and is formed by the sternum and the distal parts of the ribs and their costal cartilages. The first seven pairs of ribs are connected to the sternum by costal cartilages, the costal cartilages of the eighth to tenth ribs usually join the superjacent cartilage, and the eleventh and twelfth ribs are free (floating) at their anterior ends. The posterolateral curvature of the ribs, from their vertebral ends to their angles, produces a deep internal groove, the paravertebral gutter, on either side of the vertebral column. The ribs and costal cartilages are separated by intercostal spaces, which are deeper anteriorly and between the upper ribs. Each space is occupied by three layers of flat muscles and their aponeuroses, neurovascular bundles and lymphatic channels.

The narrow thoracic inlet (superior thoracic aperture) typically measures 5 cm anteroposteriorly and 10 cm transversely. It is bounded by the first thoracic vertebral body posteriorly, the medial border of the first ribs on each side, and the superior border of the manubrium sterni anteriorly. It slopes down and forwards, so that the apex of the lung extends upwards into the neck behind the anterior end of the first rib: structures that pass between the thorax and the upper limb therefore pass over the first rib and the apices of the lungs and the apical pleurae.

The broad thoracic outlet (inferior thoracic aperture) is limited posteriorly by the twelfth thoracic vertebral body, posterolaterally by the twelfth rib and the distal end of the eleventh rib, anterolaterally by the distal cartilaginous ends of the seventh to tenth ribs (which unite and ascend to form the costal margin), and anteriorly by the xiphoid process. It is wider in the transverse plane than in the sagittal plane and slopes obliquely downward and backward, so that the thoracic cavity is deeper posteriorly than anteriorly.

The horizontal plane that passes through the intervertebral disc between the fourth and fifth thoracic vertebrae posteriorly and the manubriosternal joint (sternal angle or angle of Louis) at the level of the second costal cartilage anteriorly is a useful aid to orientation in the thorax. It separates the superior mediastinum from the inferior mediastinum and also marks the positions of the superior limits of the pericardium and of the pulmonary trunk, the origin of the arch of the aorta, the level at which the trachea bifurcates into right and left main bronchi, and the site where the superior vena cava penetrates the pericardium to enter the right atrium.
**MUSCLES**

*Intrinsic and extrinsic muscles*

The intrinsic muscles of the chest wall are the intercostal muscles, subcostalis, transversus thoracis, levatores costarum, serratus posterior superior and serratus posterior inferior. The intercostal muscles occupy each of the intercostal spaces and are named according to their surface relations, i.e. external, internal and innermost. All except levatores costarum are innervated by the adjacent intercostal nerves derived from the ventral rami of the thoracic spinal nerves; levatores costarum are innervated by the dorsal rami of the thoracic spinal nerves. The intrinsic muscles can elevate or depress the ribs, and are active during respiration, particularly forced respiration: their primary action is believed to be to stiffen the chest wall, preventing paradoxical movement during inspiration (see Ch. 58).

The skeletal framework of the thoracic wall provides extensive attachment sites for muscles associated functionally with the neck, abdomen, back, and upper limbs. Some of them (scalenes, infrahyoid strap muscles, sternocleidomastoid, serratus anterior, pectoralis major and minor, external and internal obliques, and rectus abdominis) function as accessory muscles of respiration and are usually active only during forced respiration; scalenus medius is active in quiet inspiration. Scalenus anterior, medius and posterior are described in Chapter 28. Trapezius, latissimus dorsi, rhomboid major, rhomboid minor, levator scapulae, pectoralis major, pectoralis minor, subclavius, serratus anterior, deltoid, subscapularis, supraspinatus, infraspinatus, teres minor and teres major are described in Chapter 46. Rectus abdominis, external oblique and internal oblique are described in Chapter 61.

**Diaphragm**

The diaphragm is a curved musculotendinous sheet attached to the circumference of the thoracic outlet and to the upper lumbar vertebrae. It forms the floor of the thoracic cavity, and separates it from the abdominal cavity (see Ch. 58). The diaphragm is relatively flat centrally and domed peripherally, rising higher on the right side than on the left, an asymmetry that reflects the relative densities of the underlying liver and gastric fundus respectively. From its highest point on each side the diaphragm slopes downward to its costal and vertebral attachments: this slope is most marked posteriorly, where the space between the diaphragm and the posterior wall of the thorax is very narrow.

**Diaphragmatic openings**

The inferior vena cava passes through an opening in the central tendon of
the diaphragm to enter the right side of the mediastinum at the level of the eighth thoracic vertebra; the oesophagus passes through the muscular part of the diaphragm and enters the abdomen just to the left of the midline at the level of the tenth thoracic vertebra; and the descending thoracic aorta passes posterior to the diaphragm in the midline at the level of the twelfth thoracic vertebra (see Fig. 58.1A,B). Other structures which pass between the thorax and abdomen include the right and left vagi, phrenic and subcostal nerves, the thoracic duct, the sympathetic trunks and the thoracic splanchnic nerves, the right and left superior epigastric arteries and the hemiazygos and accessory hemiazygos veins.
THORACIC CAVITY

PLEURAL CAVITIES

The right and left pleural cavities are separate compartments on either side of the mediastinum. Each encloses a lung and its associated bronchial tree and vessels, nerves and lymphatics (see Ch. 57). The walls are formed by a serous membrane, the pleura, arranged as a closed sac. The outer layer of the sac, the parietal pleura, lines the corresponding half of the thoracic wall and covers much of the diaphragm and structures occupying the middle region of the thorax. The inner or visceral layer is more delicate and adheres closely to the pulmonary surface, following the interlobar fissures. The two layers are continuous with each other around the structures at the hila of the lungs. They remain in close, though sliding, contact at all phases of respiration. The potential space between them is the pleural cavity, which is maintained at a negative pressure by the inward elastic recoil of the lung and the outward pull of the chest wall. The lungs do not fill this space in quiet respiration, but move into recesses such as the costodiaphragmatic recess, which separates the costal and diaphragmatic pleura, in deep breathing.

The left pleural cavity is the smaller of the two pleural cavities because the heart extends further to the left.
MEDIASTINUM

The mediastinum lies between the right and left pleural sacs in and near the median sagittal plane of the chest (see Ch. 55). It extends from the sternum anteriorly to the vertebral column behind. A horizontal plane passing through the manubriosternal joint and the intervertebral disc between the fourth and fifth thoracic vertebrae separates the mediastinum into superior and inferior portions.

Superior mediastinum

The superior mediastinum lies between the manubrium sterni anteriorly, and the upper thoracic vertebrae posteriorly, and is limited laterally by the pleurae. Its inferior boundary is a slightly oblique plane that passes backward from the manubriosternal joint to the lower part of the body of the fourth thoracic vertebra. It contains the lower ends of sternohyoid, sternothyroid and longus colli on each side; the aortic arch; the brachiocephalic artery and the thoracic portions of the left common carotid and left subclavian arteries; the brachiocephalic veins and the upper half of the superior vena cava; the left highest intercostal vein; the vagus, cardiac, phrenic and left recurrent laryngeal nerves; the trachea, oesophagus, and thoracic duct; the remains of the thymus, and lymph nodes.

Inferior mediastinum

The inferior mediastinum may be divided into three parts: anterior, in front of the pericardium; middle, containing the pericardium and its contents (see Ch. 56); posterior, behind the pericardium.

Anterior mediastinum

The anterior mediastinum exists only on the left side where the left pleura diverges from the midsternal line. It is bounded anteriorly by the sternum, laterally by the pleurae, and posteriorly by the pericardium. It is narrow above, but widens a little below. Its anterior wall is formed by the left transversus thoracis and the fifth to seventh left costal cartilages. It contains a quantity of loose areolar tissue, lymphatic vessels which ascend from the convex surface of the liver, two or three anterior mediastinal lymph nodes, and the small mediastinal branches of the internal thoracic artery.

Middle mediastinum

The middle mediastinum is the broadest part of the interpleural space; it contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava with the azygos vein opening into it, the bifurcation of the trachea and the right and left principal bronchi, the
pulmonary artery dividing into its two branches, the right and left pulmonary veins and phrenic nerves, and some bronchial lymph nodes.

Posterior mediastinum

The posterior mediastinum is an irregular triangular space, bounded anteriorly by the pericardium above and the posterior surface of the diaphragm below, posteriorly by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebrae, and laterally by the mediastinal pleura. It contains the thoracic part of the descending aorta, the azygos and hemiazygos veins, the vagus and splanchnic nerves, oesophagus, thoracic duct, and lymph nodes.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ARTERIAL SUPPLY

The skin of the thorax is supplied by direct cutaneous vessels and musculocutaneous perforators which reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. Branches from the thoracoacromial axis, lateral thoracic, internal thoracic, anterior and posterior intercostal, thoracodorsal, transverse cervical, dorsal scapular and circumflex scapular arteries are the major contributing vessels (see Figs 42.4, 54.1, 54.2).

Muscles of the thoracic wall receive their blood supply from the internal thoracic artery (either directly or via the musculophrenic artery), the superior intercostal artery (from the costocervical trunk), superior thoracic artery (from the axillary artery), descending thoracic aorta, and the subcostal artery (Fig. 53.2). Additional contributions come from vessels that supply the proximal muscles of the upper limb, namely suprascapular, superficial cervical, thoracoacromial, lateral thoracic and subscapular arteries.
The detailed arterial supply of the thoracic viscera is described with the viscera.
VENOUS DRAINAGE

The intercostal veins accompany the similarly named arteries in the intercostal spaces (Fig. 53.3). The small anterior intercostal veins are tributaries of the internal thoracic and musculophrenic veins: the internal thoracic veins drain into the appropriate brachiocephalic vein. The posterior intercostal veins drain backwards and most drain directly or indirectly into the azygos vein on the right and the hemiazygos or hemiazygos veins on the left. The azygos veins exhibit great variation in their origin, course, tributaries, anastomoses and termination.
Fig. 53.3 Veins of the thoracic wall and azygos system.

(From Drake, Vogl, Mitchell, Tibbitts and Richardson 2008.)
LYMPHATIC DRAINAGE

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Fig. 54.19). Lymph vessels from deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymphatic nodes.
INNERVATION

THORACIC SPINAL NERVES

There are twelve pairs of thoracic spinal nerves. The ventral rami, unlike their cervical and lumbar counterparts, have retained a largely segmental distribution to the body wall (see Figs 15.12, 54.3, 54.20). The upper eleven lie between the ribs (intercostal nerves), and the twelfth lies below the last rib (subcostal nerve). Each is connected with the adjoining ganglion of the sympathetic trunk by pre- and postganglionic branches (white and grey rami communicantes respectively). Intercostal nerves are distributed primarily to the thoracic and abdominal walls. The greater part of the first thoracic ventral ramus passes into the brachial plexus, together with a variable proportion of the second. The next four ventral supply only the thoracic wall, and the lower five supply both thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and the gluteal skin. Communicating branches link the intercostal nerves posteriorly in the intercostal spaces, and the lower five nerves communicate freely in the abdominal wall. Thoracic dorsal rami divide into medial and lateral branches that supply the intrinsic muscles of the back and the overlying postvertebral skin on a segmental basis (see Ch. 42).

The supraclavicular branches of C4 from the cervical plexus innervate the skin over the clavicle and may communicate with the anterior cutaneous branches of the second thoracic ventral ramus (see Ch. 28).
AUTONOMIC INNERVATION

The autonomic nervous system in the thorax consists of right and left sympathetic trunks and vagus nerves and the cardiac, oesophageal and pulmonary plexuses.

**Sympathetic trunks**

The ganglionated sympathetic trunks lie anterior to the heads of the ribs; the ganglia are arranged segmentally (see Fig. 55.7). Preganglionic sympathetic axons originate from neurones in the lateral grey column of the spinal cord from T1 to L2, and leave the spinal cord with the corresponding ventral roots as white rami communicantes. Their targets vary. Some enter the sympathetic trunk, where they either synapse in their segmental ganglion or ascend or descend in the trunk to synapse in cervical or lumbar ganglia. Many of the preganglionic axons which originate in the lower thoracic spinal segments (T5–12) do not synapse locally but enter the abdominal cavity as the thoracic splanchnic nerves and synapse either in prevertebral ganglia, especially the coeliac ganglion, or around the medullary chromaffin cells of the suprarenal gland (see Ch. 72). Axons destined for the cervical ganglia are derived from preganglionic neurones in T1.

**Vagus nerves in the thorax**

Preganglionic parasympathetic fibres arise from neuronal cell bodies in the dorsal motor nucleus of the vagus in the medulla. Those destined for the thoracic viscera travel in the pulmonary, cardiac and oesophageal branches of the vagus and synapse in minute ganglia in the visceral walls. Axons traveling in cardiac branches join the cardiac plexuses and synapse in ganglia distributed over both atria: when stimulated, they slow the cardiac cycle (see Ch. 60). Pulmonary branches contain axons which relay in ganglia of the pulmonary plexuses and are motor (bronchoconstrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles and secretomotor to the mucous glands of the respiratory epithelium.

**Autonomic plexuses in the thorax**

**Cardiac plexus**

The cardiac plexus has a superficial component inferior to the aortic arch, lying between it and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation (see Ch. 56). The superficial part is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the lower of the two cervical cardiac branches of the left vagus. The deep part is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The
only cardiac nerves which do not join it are those that join the superficial part of the plexus. Branches from the cardiac plexuses also form the left and right coronary plexuses and the atrial plexuses.

Pulmonary plexus

The pulmonary plexuses are anterior and posterior to the other structures at the hila of the lungs (see Ch. 57). They are formed by cardiac branches from the second to fifth (or sixth) thoracic sympathetic ganglia and from the vagus, and from cervical sympathetic cardiac nerves. The left plexus also receives branches from the left recurrent laryngeal nerve.

Oesophageal plexus

The oesophageal plexus surrounds the oesophagus below the level of the lung roots (see Ch. 55). Vagal fibres either pass through the plexus or are given off directly by the vagus in the thorax. All fibres relay in the oesophageal wall and are motor to the smooth muscle in the lower oesophagus and secretomotor to mucous glands in the oesophageal mucosa. Vasomotor sympathetic fibres arise from the upper six thoracic spinal cord segments. Those from the upper segments synapse in cervical ganglia; postganglionic axons innervate the vessels of the cervical and upper thoracic oesophagus. Fibres from the lower segments pass directly to the oesophageal plexus or to the coeliac ganglion, where they synapse; postganglionic axons innervate the vessels of the distal oesophagus.
SURFACE ANATOMY

BREAST

In females, the site of the nipple is dependent on the size and shape of the breasts. In the male, the nipple is usually sited in the fourth intercostal space in the midclavicular line. In the young adult of either sex, the nipples are usually positioned 20–23 cm from the jugular notch in the midclavicular line and 20–23 cm apart in the horizontal plane.
SKELETAL LANDMARKS

Anteriorly, the clavicle and sternoclavicular joint are not only palpable, but also visible in all but the most obese individuals (Fig. 53.4). The sternum can be felt throughout its length in the midline, but laterally it may be obscured by pectoralis major. The jugular notch (suprasternal notch) at the superior end of the sternum is easily found, and the trachea may be felt deep to it. The cartilaginous rings are usually palpable: by rolling one’s finger over the trachea, or by using two fingers within the notch, it is possible to assess whether the trachea is in the midline or deviated to one side. The jugular notch lies at the level of the junction between the second and third thoracic vertebrae. The manubriosternal angle is more pronounced in the male than in the female, and is felt at the junction of the manubrium with the body of the sternum. It is a particularly useful landmark because it indicates the medial ends of the second costal cartilages, and is level with the junction of the fourth and fifth thoracic vertebrae. The xiphisternal joint and xiphoid process may be felt at the inferior end of the sternum. The joint usually lies at the level of the ninth thoracic vertebra. Lateral to this, may be felt the costal margin, formed here by the anterior ends of the seventh costal cartilages. The rest of the costal margin is formed by the fused anterior ends of the eighth, ninth and tenth costal cartilages, whereas posteriorly the free ends of the eleventh and twelfth ribs may be palpable. In thin individuals, it is possible to palpate all the ribs from the first down to the costal margin. However, well-developed musculature or the female breast will obscure the ribs anteriorly and the shaft of the first rib (which lies predominantly behind the clavicle).

(Photo by permission from Lumley JSP 2002 Surface Anatomy, 3rd edn. Edinburgh: Churchill Livingstone.)

Posteriorly (Fig. 53.5), the spinous processes of the thoracic vertebrae are easily palpable; the posterior angles of the ribs can be felt lateral to the spinous processes. The surface anatomy of the back and skeletal surface landmarks are described in Chapters 42 and 43.

Auscultatory triangle. 7. Latissimus dorsi. 8. External oblique. 9. Lumbar triangle. 10. Gluteus medius. 11. Gluteus maximus.

(Photograph courtesy of Lumley JSP 2002 Surface Anatomy, 3rd edn. Edinburgh: Churchill Livingstone.)
MUSCULOTENDINOUS LANDMARKS

In a muscular subject, pectoralis major, the slips of serratus anterior, and latissimus dorsi, trapezius, external oblique and rectus abdominis are all easily visible. The anterior chest wall of females may be largely obscured by the breasts.
INTRATHORACIC VISCERA

Anteriorly, the manubriosternal joint overlies the concavity of the aortic arch and marks the level at which the trachea bifurcates and the azygos vein enters the superior vena cava. The costal cartilages of the second ribs meet the sternum here, and so the joint offers an accurate point at which to start counting ribs. The transverse thoracic plane, which includes the sternal angle, demarcates the lower border of the superior mediastinum and the point at which the aortic arch receives the ascending aorta (anteriorly) and becomes the descending aorta (posteriorly). At this point, the right and left pleurae are in contact with each other; it is therefore a useful starting point when delineating the surface markings of the parietal pleura (Fig. 53.6A,B).
Fig. 53.6 A. Relation of the pleura and lungs to the chest wall: right lateral aspect. B. Lower limits of the lung and pleura: posterior view. The lower portions of the lung and the pleura are shown on the right side.

Heart

The surface projections to be described below apply to an average adult. It must be appreciated that they are considerably modified by age, sex, stature and proportions, ventilation and posture. The projections of the position of the valves on the surface are not the best sites for their auscultation. The cardiac apex almost corresponds to the apex beat, which is usually visible and
always palpable in the fifth intercostal space, slightly medial to the midclavicular line, 9 cm from the midline in average adult males. The apex beat is the most inferolateral point at which a pulsation can be felt; however, the true cardiac apex is a short distance further inferolaterally and does not contact the thoracic wall in systole.

The cardiac sternocostal surface, projected onto the anterior thoracic wall, is a trapezoid. The area of superficial cardiac dullness as mapped out by light percussion is roughly triangular and corresponds to the area of the heart not covered by lung. The borders of the heart, although frequently given as being fixed, are in fact variable and depend largely on the position of the diaphragm and the obesity and build of the patient.

The following borders are usually recognized. The upper border forms a gently sloping line from the second left costal cartilage to the third right costal cartilage. The right border is a gently curved line, convex to the right from the third right to the sixth right costal cartilage, usually 1–2 cm lateral to the sternal edge. The inferior or acute border runs from the sixth right costal cartilage to the apex of the heart, which lies in the fifth left intercostal space approximately in the midclavicular line. The left ('obtuse') border extends superomedially, convex laterally, from the apex to meet the second left costal cartilage 1 cm from the left sternal edge. An oblique line joining the sternal end of the third left and sixth right costal cartilages represents the anterior part of the coronary sulcus, which separates the right atrium from the right ventricle (the left atrium lies behind the heart). The left and right borders can be identified by heavy percussion.

The surface projection of the anterior part of the atroventricular groove is an oblique line that joins the sternal ends of the third left and sixth right costal cartilages and separates the atrial and ventricular areas. Although in different planes, the projections of the cardiac valves are also sited along or close to this line (see Fig. 56.6).

The pulmonary orifice lies partly behind the superior border of the third left costal cartilage, and partly behind the left third of the sternum. It is represented by a horizontal line, 2.5 cm long, which crosses cartilage and sternum. Parallel lines from the ends of this line, up to the second left costal cartilage, indicate the site of the pulmonary trunk.

The aortic orifice is below and a little right of the pulmonary, and is marked by a line, 2.5 cm long, running from the medial end of the third left intercostal space downward to the right. Two parallel lines from the ends of this line, slanting up to the right half of the manubrio-sternal joint, outline the location of the ascending aorta.

The tricuspid valvar orifice is represented by a line, 4 cm long, starting near
the midline just below the level of the fourth right costal cartilage, and passing down and slightly to the right. The centre of this line should be level with the middle of the fourth right intercostal space.

The mitral orifice is behind the left half of the sternum opposite the fourth left costal cartilage, and is represented by a line, 3 cm long, descending to the right.

The sites of auscultation for the cardiac valves do not correspond directly to the surface anatomy of the valves, because the intensity of the sounds is influenced by direction of blood flow, which carries the sound with it. Thus, convenient sites at which to apply the stethoscope bell or diaphragm are: the sternal end of the second left intercostal space (pulmonary area); the sternal end of the second right intercostal space (aortic area); near the cardiac apex (mitral area); and over the left lower sternal border, at the level of the fifth intercostal spaces (tricuspid area) (see Fig. 56.6).

**Great vessels**

The aortic arch lies predominantly behind the manubrium sterni. Starting at the aortic valve (behind the lower border of the third left costal cartilage), the ascending aorta curves forwards, upwards and to the right, to become the aortic arch behind the right half of the manubrium at the level of the second right costal cartilage. It continues to ascend behind the right side of the manubrium sterni, arching over the transthoracic plane and descending such that the aortic knuckle protrudes just to the left of the manubrium sterni in the first intercostal space. The pulmonary trunk and tracheal bifurcation lie within its concavity. The brachiocephalic artery arises approximately behind the centre point of the manubrium and ascends to the right sternoclavicular joint. The superior vena cava descends predominantly behind, but also just to the right of, the right manubrial border and enters the right atrium at the level of the third right costal cartilage. The short right brachiocephalic vein descends almost vertically from behind the medial end of the clavicle just lateral to the right sternoclavicular junction, whereas the much longer left brachiocephalic vein passes almost horizontally behind the superior portion of the manubrium sterni. Both join behind the first right costal cartilage to form the superior vena cava, which descends as a band, 2 cm wide, along the right sternal margin, reaching the right atrium at the level of the third right costal cartilage.

**Lungs and pleurae**

Anteriorly, the apex of the lung is approximately 2.5 cm above the centre of the medial one-third of the clavicle; posteriorly, it lies at the level of the seventh cervical vertebra. The surface markings of the apical dome and costovertebral border of the lung correspond to those of the parietal pleura. The anterolateral surface projection of the lung may be represented by a
curved line that crosses the midclavicular line at the level of the sixth rib, and
the midaxillary line at the level of the eighth rib. On inspiration, the lower
border of the lung moves downwards, from the level of the tenth thoracic
vertebra to the level of the twelfth thoracic vertebra (these levels are
approximate). In full expiration, the lower border of the lung retreats anteriorly
a short distance from the retrosternal costomediastinal recess; laterally, the
lower margin of the lung may rise 5 cm above the parietal pleural reflection
(the costodiaphragmatic recess).

**Trachea, bronchi**

The trachea originates at the level of the cricoid cartilage (C6), and usually
runs in the midline. It is palpable within the suprasternal notch, where it may
be felt either by rolling one finger over its convex surface or by defining its
lateral extent with two fingers. A shift to one side indicates that the
mediastinum has either been pulled over to that side by loss of lung volume,
or pushed over, e.g. by a large pneumothorax or pleural effusion. The
trachea bifurcates at the level of the sternal angle; the posterior landmark for
the bifurcation is the fourth thoracic vertebra.

**Fissures**

On either side, the upper and lower lobes of the lung are separated by the
oblique fissure. This may be marked by a line running from the posterior end
of the third rib downwards and forwards to cross the fifth rib in the midaxillary
line and then to the sixth costal cartilage at the midclavicular line (7–8 cm
lateral to the midline). As a convenient approximation, the oblique fissure
follows the medial border of the scapula when the arm is in full abduction.
The left oblique fissure is slightly more vertical than the right.

The horizontal fissure, between the middle and upper lobes, lies at the level
of the fourth costal cartilage on the right. It starts from the anterior border of
the lung and passes posterolaterally to meet the oblique fissure: the
horizontal fissure therefore extends from the fifth rib in the midaxillary line to
the fourth rib at the right sternal border. The upper and middle lobes lie
anterior to the oblique fissure and so are best examined from the front of the
chest, whereas the lower lobes lie posteriorly and should be examined from
the back of the chest. The right middle lobe may be projected onto the chest
wall as a triangular surface, where the three points of the triangle are
represented by the fourth rib at the right parasternal edge, the fifth rib at the
midaxillary line, and the sixth rib at the midclavicular line.

**Pleural reflections**

Starting in the midline at the manubriosternal joint, the anterior reflections of
the parietal pleura may be traced superiorly along a line that diverges from
the midline and extends up and outwards to the apex of the pleural cavity. This point lies 3–4 cm above the anterior end of the first rib, on a level with the posterior end of the rib; its surface marking is usually 2.5 cm above the centre of the medial one-third of the clavicle. The parietal pleura is intimately fused with the inner aspect of the thoracic cavity, and it can be followed laterally and inferiorly down the inner aspect of the chest wall to the level of the tenth rib in the midaxillary line. Followed medially, the pleura covers the diaphragm; its position will therefore vary according to the phase of ventilation.

The costodiaphragmatic reflections of the pleurae can be followed anteriorly from the midaxillary line towards the midline. On the right, the pleura crosses the eighth rib in the midclavicular line, passes to the xiphisternum and then ascends to the manubriosternal joint. On the left, the pleura does not reach the midline, but turns superiorly at the anterior end of the sixth rib, 3–5 cm from the midline, and passes up to the level of the fourth costal cartilage. This deviation produces an area between the heart and the sternum that is free of pleura; a needle puncture of the heart may be performed at this site without risk of damaging the pleura. The right and left pleurae meet at the level of the fourth costal cartilage and maintain contact up to the level of the second costal cartilage.

Viewed from the back, the medial edge of the pleura may be followed along a line joining the transverse processes of the second to the twelfth thoracic vertebrae. It extends horizontally laterally, and crosses the twelfth and eleventh ribs to meet the tenth rib in the midaxillary line (Fig. 53.6A,B).
CHAPTER 54 – Chest wall and breast

The chest wall surrounds the thoracic cavity. The skin and soft tissue cover a musculoskeletal frame consisting of 12 pairs of ribs which articulate with 12 thoracic vertebrae posteriorly, and (except for the last two pairs of ribs) with the sternum anteriorly, via their costal cartilages; intrinsic muscles and muscles which connect the chest wall with the upper limb and the vertebral column; numerous blood and lymphatic vessels and nerves which supply the components of the musculoskeletal frame and the overlying skin and breast tissue.

SKIN AND SOFT TISSUE

SKIN

Vascular supply

Arteries

The skin of the thorax is supplied by a combination of direct cutaneous vessels and musculocutaneous perforators which reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. Branches from the thoracoacromial axis, lateral thoracic artery, internal thoracic artery, anterior and posterior intercostal arteries, thoracodorsal, transverse cervical/dorsal scapular and circumflex scapular arteries are the major contributing vessels (Figs 54.1, 54.2; see Fig. 42.4).
Fig. 54.1 Anatomical territories of cutaneous blood vessels on the anterior trunk.
(By permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps, 2nd edn. Edinburgh: Churchill Livingstone.)
The anterior aspect of the thoracic skin is supplied by the thoracoacromial axis, the internal thoracic arteries, perforating branches from the intercostal arteries and branches from the lateral thoracic and superficial thoracic arteries. The thoracoacromial axis supplies the skin primarily via musculocutaneous perforators from its pectoral branch, which reach the skin through pectoralis major. In addition, direct cutaneous branches arise from the acromial and deltoid branches. The internal thoracic artery sends direct perforating branches to the skin of the upper six intercostal spaces, accompanied by the cutaneous branches of the anterior intercostal nerves. The branches reach the skin after passing through pectoralis major and travelling laterally in the subcutaneous fat as direct cutaneous vessels: the second
intercostal perforator is usually the largest.

The lateral aspect of the thoracic skin is supplied by the lateral thoracic, superficial thoracic and lateral cutaneous branches of the intercostal arteries. The lateral thoracic artery gives off direct cutaneous branches to the lateral chest wall in addition to musculocutaneous branches that pass through pectoralis major.

The posterior aspect of the thoracic skin is supplied by the medial and lateral dorsal cutaneous branches of the posterior intercostal arteries (which reach the skin by passing through erector spinae and latissimus dorsi), musculocutaneous perforating branches from the superficial cervical artery and the transverse cervical/dorsal scapular artery (via trapezius), musculocutaneous perforating branches from the thoracodorsal artery and the intercostal arteries (via latissimus dorsi), and direct cutaneous branches from the circumflex scapular artery.

**Veins**

The intercostal veins accompany the similarly named arteries in the intercostal spaces (see Fig. 53.3). The small anterior intercostal veins are tributaries of the internal thoracic and musculophrenic veins; the internal thoracic veins drain into the appropriate brachiocephalic vein. The posterior intercostal veins drain backwards and most drain directly or indirectly into the azygos vein on the right and the hemiazygos or accessory hemiazygos veins on the left. The azygos veins exhibit great variation in their origin, course, tributaries, anastomoses and termination (see Ch. 55).

**Lymphatic drainage**

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see p. 928, Figs 54.19, 54.21). Lymph vessels from the deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymphatic nodes.
Fig. 54.19  The relations of the breast.
(From Drake, Vogl and Mitchell 2005.)
Innervation

The skin of the thorax is supplied by cutaneous branches of cervical and thoracic nerves in consecutive, curved zones, the upper almost horizontal and the lower oblique. On the upper ventral thoracic aspect, the third and fourth cervical areas adjoin the first and second thoracic areas (Fig. 54.3; see Fig. 42.3) because the intervening nerves provide the sensory and motor supply to the upper limb. There is a similar, but less extensive, posterior ‘gap’: most of the skin of the back of the thorax is supplied by the dorsal rami of the thoracic nerves. The subcostal margin is supplied by the seventh thoracic nerve.
The ventral rami of the first to the eleventh thoracic nerves pass into the intercostal spaces. Each intercostal nerve gives off a lateral cutaneous branch, which arises beyond the angle of the ribs and divides into anterior and posterior branches, and terminates near the sternum in an anterior cutaneous branch (see Fig. 54.18).
Branches of the supraclavicular nerve, which originates from the third and fourth cervical nerve roots, supply the skin in the upper pectoral region. Most of the first thoracic nerve joins the brachial plexus: it gives off a small inferior branch, which becomes the first intercostal nerve. The lateral cutaneous branch of the second intercostal nerve supplies the skin of the axilla and is known as the intercostobrachial nerve. The costal margin is supplied by a branch from the seventh thoracic nerve, and the tenth thoracic nerve supplies the skin of the abdomen at the level of the umbilicus. The seventh to eleventh thoracic nerves supply the skin of the thoracic wall as they pass anteriorly and inferiorly; they continue beyond the costal cartilages and supply the skin and subcutaneous tissues of the abdominal wall. The subcostal nerve follows the inferior border of the twelfth rib and supplies the skin of the lower abdominal wall (Fig. 54.3).
SOFT TISSUE

Superficial fascia

The superficial fascia lies below the skin. It consists primarily of fat and is only loosely attached to the skin, an arrangement that allows some movement of the underlying structures. Small blood vessels and nerves perforate the superficial fascia to supply the skin.

The breast lies within the superficial fascia and is described later in this chapter.

Deep fascia

The deep fascia is a tough and fibrous membrane that allows some movement of structures over one another.

Clavipectoral fascia

The clavipectoral fascia is a sheet of deep fascia that extends between the clavicle and pectoralis minor, surrounds subclavius and extends medially to the first rib.
BONE AND CARTILAGE

The 12 thoracic vertebrae and their associated intervertebral discs are described in detail in Chapter 42.

STERNUM

The sternum consists of a cranial manubrium, an intermediate body (mesosternum) and a caudal xiphoid process (Figs 54.4, 54.5). Until puberty, the mesosternum consists of four sternabrae, which, from their costal relations, appear to be intersegmental. The total length of the sternum is approximately 17 cm in males, less in females. The ratio between manubrial and mesosternal lengths differs between the sexes. Growth may continue beyond the third decade and possibly throughout life.

In natural stance, the sternum slopes down and slightly forwards. It is convex in front, concave behind, and broadest at the junction with the first costal cartilages. It is narrow at the manubriosternal joint, below which it widens to its articulation with the fifth cartilages, and narrows again below this.
The sternum contains highly vascular trabecular bone enclosed by a compact layer that is thickest in the manubrium between the clavicular notches. Centrally, the bone is lightly constructed, whereas laterally the trabeculae are thicker and wider. The medulla contains haemopoietic bone marrow.

**Manubrium**

The manubrium is level with the third and fourth thoracic vertebrae. It is broad and thick above, and narrows to its junction with the body. The anterior surface is smooth, transversely convex and vertically concave, and the posterior surface is concave and smooth. The superior border is thick, and contains a central jugular (suprasternal) notch between two oval fossae, the clavicular notches, which are directed up and posterolaterally for articulation with the sternal ends of the clavicles. Fibres of the interclavicular ligament are attached to the jugular notch. The inferior border, oval and rough, carries a thin layer of cartilage for articulation with the body. The lateral borders are marked above by a depression for the first costal cartilage and below by a small articular demifacet, which articulates with part of the second costal cartilage. The narrow curved edge descends medially between these facets.

Unlike all the other sternocostal joints, the manubriocostal joint between the manubrium and the first costal cartilage is an unusual form of synarthrosis.

**Body**

The body is level with the fifth to ninth thoracic vertebrae. It is longer, narrower and thinner than the manubrium, and is broadest near its lower end. The anterior surface is nearly flat and faces slightly upwards. It bears three variable transverse ridges, which mark the levels of fusion of its four sternebrae. A sternal foramen, of varying size and form, may occur between the third and fourth sternebrae. The posterior surface, slightly concave, also displays three less distinct transverse lines. The oval upper end articulates with the manubrium at the level of the sternal angle (manubriosternal joint), which lies opposite the inferior border of the fourth vertebral body. The manubriosternal joint is marked by a posterior transverse groove and is palpable anteriorly as a ridge (Fig. 54.5).

The lower end of the body is narrow and continuous with the xiphoid process. On each lateral border, at its superior angle, a small notch articulates with part of the second costal cartilage (Fig. 54.4). Below this, four costal notches articulate with the third to sixth costal cartilages. The inferior angle bears a small facet which, together with the xiphoid process, articulates with the seventh costal cartilage. Between these articular depressions, a series of curved edges diminish in length downwards and form the anterior limits of the intercostal spaces.

**Xiphoid process (xiphisternum)**

The xiphoid process is in the epigastrium. It is the smallest and most variable sternal element, and may be broad and thin, pointed, bifid, perforated, curved or deflected. The xiphoid is cartilaginous in youth, but more or less ossified in adults. It is continuous with the lower end of the body at the xiphisternal joint. Anterior to its superolateral angles there are demifacets that articulate with parts of the seventh costal cartilages (Fig. 54.5).
Muscle attachments

The sternal ends of pectoralis major and sternocleidomastoid are attached to the anterior surface of the manubrium. Sternothyroid is attached to the posterior surface, opposite the first costal cartilage, and the most medial fibres of sternohyoid are attached above sternothyroid. The articular capsules of the sternocostal joints and sternal fibres of pectoralis major are attached to the anterior surface of the body. Transversus thoracis (sternocostalis) is attached to its posterior surface. The external intercostal membranes are attached to the borders of the body between the costal facets. The most medial fibres of rectus abdominis and the aponeuroses of external and internal oblique are attached to the anterior surface of the xiphoid. The linea alba is attached to its lower end, and the aponeuroses of internal oblique and transversus abdominis are attached to its borders. Slips of the diaphragm are attached to its posterior aspect, and the sternum is here related to the liver.

Vascular supply

The internal thoracic artery provides the main blood supply for the sternum. A sternal network of vessels derived from the internal thoracic arteries provides a network of perforating arteries at the level of each intercostal space. An anterior network formed by anastomoses between anterior superior and anterior inferior sternal branches and laterosternal and anterosternal arches provides branches that go directly into the sternum. A similar network of vessels exists posteriorly and is formed by anastomoses between posterior superior and posterior inferior vessels and laterosternal and retrosternal arches. The posterior network is more highly developed than the anterior system; these networks are particularly developed at the level of the fourth and fifth intercostal spaces.

The venous network is less developed and formed mainly by large vessels. The inframedullary network of sinuses form a network in the bone and then drain into the venous system. They are transcortical veins, and drain either into the peripheral sternal networks or into the internal thoracic vein.

Innervation

The manubrium is supplied by the anterior branch of the supraclavicular nerve and the anterior cutaneous branch of the first intercostal nerve, whereas the body of the sternum is supplied largely by anterior branches of the intercostal nerves. The anterior branch of the phrenic nerve runs anteromedially from the diaphragm and supplies the lower portion of the sternum with its contralateral counterpart.

Ossification

The sternum is formed by fusion of two cartilaginous sternal plates flanking the median plane. The arrangement and number of centres of ossification vary according to the level of completeness and time of fusion of the sternal plates, and to the width of the adult bone. Incomplete fusion leaves a sternal foramen. The manubrium is ossified from one to three centres appearing in the fifth fetal month. The first and second sternebrae usually ossify from single centres that appear at about the same time (Fig. 54.6A). Centres in the third and fourth sternebrae are commonly paired, and appear in the fifth and sixth months, respectively, but one of either pair may be delayed until the seventh or even eighth month, and the fourth sternebral centre may
be absent. The xiphoid process begins to ossify in the third year or later. In some sternae, all centres are single and median; in others, the manubrial centre is single and the sternebral centres are all paired, symmetric or asymmetric. Union of mesosternal centres begins at puberty and proceeds from below upwards: by the age of 25 years, they are all united (Fig. 54.6B).
Suprasternal ossicles, paired or single, occur sometimes. They may fuse to the manubrium or articulate posteriorly at the lateral border of the jugular notch. When well formed, they are pyramidal, and their base is articular. The ossicles are cartilaginous at birth, and ossify during adolescence.

Pectus excavatum and carinatum

Pectus excavatum occurs to some extent in about 1 in 500 live births. It is a depression of the sternum and costal cartilage that results in a funnel-shaped chest. The lower costal cartilages and the body of the sternum are depressed and there is some asymmetric curving of the ribs posteriorly. There is frequently an abnormal posture with dorsal lordosis, and some patients also develop a scoliosis. The deformity is either found at birth or occurs early in life: the majority of affected individuals show signs of the abnormality in the first 12 months of life. The aetiology is unknown, but some cases are associated with conditions such as Marfan's syndrome, in which the connective tissue is abnormal.

Pectus carinatum is the anterior protrusion of the sternum or a pigeon chest. The deformity is less common than pectus excavatum, and although present in early childhood, it usually progresses during adolescence and then remains the same from age 18 throughout adulthood.
CLAVICLE

The clavicle is described in Chapter 46.
The ribs are 12 pairs of elastic arches (Fig. 54.7). They articulate posteriorly with the vertebral column and form the greater part of the thoracic skeleton. Their number may be increased by cervical or lumbar ribs or reduced by the absence of the twelfth pair. The first seven pairs are connected to the sternum by costal cartilages, and are referred to as the true ribs. The remaining five are the so-called false ribs: the cartilages of the eighth to tenth usually join the superjacent costal cartilage, whereas the eleventh and twelfth ribs, which are free at their anterior ends, are sometimes termed the ‘floating’ ribs. The tenth rib may also be a floating rib; the incidence varies from 35% to 70% in different races.

The ribs are separated by the intercostal spaces, which are deeper in front and between the upper ribs. The latter are less oblique than the lower ribs; obliquity is maximal at the ninth rib and decreases to the twelfth. Ribs increase in length from the first to seventh, and thereafter diminish to the twelfth. They decrease in breadth
downwards; in the upper ten, the greatest breadth is anterior. The first two and last three ribs present special features, whereas the remainder conform to a common plan.

Ribs consist of highly vascular trabecular bone, enclosed in a thin layer of compact bone and containing large amounts of red marrow.

**Typical rib**

A typical rib has a shaft with anterior and posterior ends (Fig. 54.8). The anterior, costal, end has a small concave depression for the lateral end of its cartilage. The shaft has an external convexity and is grooved internally near its lower border, which is sharp, whereas its upper border is rounded. The posterior, vertebral, end has a head, neck and tubercle. The head presents two facets, separated by a transverse crest. The lower and larger facet articulates with the body of the corresponding vertebra, its crest attaching to the intervertebral disc above it. The neck is the flat part beyond the head, anterior to the corresponding transverse process. It is oblique, and faces anterosuperiorly. Its posteroinferior surface is rough and pierced by foramina. Its upper border is the sharp crest of the neck, its lower border rounded. The tubercle, which is more prominent in upper ribs, is posteroexternal at the junction of the neck and shaft and is divided into medial articular and lateral non-articular areas. The articular part bears a small, oval facet for the transverse process of the corresponding vertebra. The nonarticular area is roughened by ligaments. The shaft is thin and flat and has external and internal surfaces, and superior and inferior borders. It is curved, bent at the posterior angle (5–6 cm from the tubercle), and twisted about its long axis. The part behind the angle inclines superomedially, and so its external surface is posteroinferior. In front of the angle it faces slightly up. It is convex and smooth, and near the tubercle is crossed by a rough line, directed inferolaterally, towards the posterior angle. The smooth internal surface is marked by a costal groove, bounded below by the inferior border. The superior border of the groove continues behind the lower border of the neck, but terminates anteriorly at the junction of the middle and anterior thirds of the shaft, anterior to which the groove is absent.
Attachments and relations

A radiate ligament is attached along the anterior border of the head and an intra-articular ligament is attached to the crest of the head. The anterior surface of the head is related to costal pleura and, in lower ribs, to the sympathetic trunk. The anterior surface of the neck is divided by a faint transverse ridge for the internal intercostal membrane and is continuous with the inner lip of the superior border of the shaft. The area above the ridge, which is more or less triangular, is separated from the membrane by fatty tissue. The lower, smooth area is covered by costal pleura. The posterior surface of the neck gives attachment to the costotransverse ligament and is
pierced by vascular foramina. The superior costotransverse ligament is attached to the crest of the neck, which extends laterally into the outer lip of the superior border of the shaft. The rounded inferior border of the neck continues laterally into the upper border of the costal groove, and gives attachment to the internal intercostal membrane. The articular area of the tubercle in the upper six ribs is convex and faces posteromedially. In the succeeding three or four ribs it is almost flat, and faces down, back and slightly medially. The lateral costotransverse ligament is attached to the non-articular area.

The ridge on the external surface of the shaft (near its posterior angle) gives attachment to an upward continuation of the thoracolumbar fascia and lateral fibres of iliocostalis thoracis. From the second to the tenth ribs, the distance between angle and tubercle increases. Medial to the angle, the external surface gives attachment to a levator costae and is covered by erector spinae. Near the sternal end of this surface an indistinct oblique line, the anterior ‘angle’, separates the attachments of external oblique and serratus anterior (or latissimus dorsi, in the case of the ninth and tenth ribs). The internal intercostal muscle is attached to the costal groove on the internal surface, and separates the bone and the intercostal neurovascular bundle. At its vertebral end, the groove faces down, its borders in the same plane. The shaft broadens near the posterior angle, and the groove reaches its internal surface. The innermost intercostal is attached to the superior rim of the groove, and this attachment occasionally extends to the anterior quarter of the rib. Posteriorly, the superior rim meets the lower border of the neck. The external intercostal muscle is attached to the sharp inferior costal border. The superior border has two lips posteriorly: an inner and an outer lip. The internal intercostal muscles and the innermost intercostal muscles are attached to the inner lip. The external intercostal muscle is attached to the outer lip.

Vascular supply and innervation

Typical ribs receive their blood supply anteriorly via branches from the internal thoracic artery (first six intercostal spaces) or musculophrenic artery (subsequent spaces), and posteriorly from intercostal arteries derived directly from the aorta. Venous drainage is into the corresponding intercostal vein and then into the azygos system. Typical ribs are innervated segmentally by branches from the corresponding intercostal nerves.

Cervical rib

A cervical rib, the costal element of the seventh cervical vertebra, may be a mere epiphysis on its transverse process, but more often it has a head, neck and tubercle. When a shaft is present, it is of variable length, and extends anterolaterally into the posterior triangle of the neck, where it may end freely or join the first rib or costal cartilage, or even the sternum. A cervical rib may be partly fibrous, but its effects are not related to the size of its osseous part. If it is long enough, its relations are those of a first thoracic rib: the brachial plexus (usually lower trunk) and subclavian vessels are superior and apt to suffer compression in a narrow angle between the rib and scalenus anterior. Hence, cervical ribs may first be revealed by nervous and vascular symptoms, particularly those caused by pressure on the eighth cervical and first thoracic spinal nerves.
A cervical rib or pleurapophysis may show synostosis or diarthrosis with either the anterior (parapophysial) or posterior (diapophysial) 'roots' of the so-called seventh cervical transverse process or, more usually, with both.

**First rib**

Most acutely curved and usually shortest, the first rib is broad and flat, its surfaces are superior and inferior, and its borders are internal and external (Fig. 54.8). It slopes obliquely down and forwards to its sternal end. The obliquity of the first ribs accounts for the appearance of pulmonary and pleural apices in the neck.

The head of the first rib is small and round. It bears an almost circular facet, and articulates with the body of the first thoracic vertebra. The neck is rounded and ascends posterolaterally. The tubercle, wide and prominent, is directed up and backwards; medially, an oval facet articulates with the transverse process of the first thoracic vertebra. At the tubercle, the rib is bent, its head turned slightly down, and so the angle and tubercle coincide. The superior surface of the flattened shaft is crossed obliquely by two shallow grooves, separated by a slight ridge, which usually ends at the internal border as a small pointed projection, the scalene tubercle, to which scalenus anterior is attached. The groove anterior to the scalene tubercle forms a bed for the subclavian vein, and the rough area between this and the first costal cartilage gives attachment to the costoclavicular ligament and, more anteriorly, to subclavius. The subclavian artery and (usually) the lower trunk of the brachial plexus pass in the groove behind the tubercle. Behind this, scalenus medius is attached as far as the costal tubercle.

The external border is convex, thick posteriorly and thin anteriorly. It is covered behind by scalenus posterior descending to the second rib. The first digitation of serratus anterior is, in part, attached to it, behind the subclavian (arterial) groove. The internal border is concave and thin, and the scalene tubercle is near its midpoint. The supracleural membrane, which covers the cervical dome of the pleura, is attached to the internal border. The inferior surface is smooth. The anterior end is larger than in any other rib.

**Vascular supply and innervation**

The first rib is supplied by the internal thoracic artery and the superior intercostal artery. Venous drainage is via the intercostal vein. The rib is innervated by the first intercostal nerve.

**Ossification**

The first rib has a primary centre for the shaft, and secondary ossification centres for the head of the rib and the tubercle.

**Second rib**

The second rib is twice the length of the first rib, and has a similar curvature. The non-articular area of the tubercle is small. The angle is slight and near the tubercle. The shaft is not twisted, but at the tubercle is convex upwards, as in the first rib, but less so. The external surface of the shaft is convex and superolaterally is marked centrally by a rough, muscular impression that continues posteromedially towards the tubercle
as a narrow, roughened ridge. The internal surface, smooth and concave, faces inferomedially and there is a short costal groove posteriorly.

The lower parts of the first and second digitations of serratus anterior are attached to a rough prominence that extends from just behind the midpoint of the external surface (Fig. 54.8). The distinct lips of the upper border are widely separated behind; scalenus posterior and serratus posterior superior are attached to the outer lip in front of the angle.

Vascular supply and innervation

The blood supply of the second rib is the internal thoracic artery and the superior intercostal artery. Venous drainage is via the superior intercostal vein, which drains into the brachiocephalic vein, and the anterior intercostal veins, which drain into the internal thoracic vein. The bone is innervated by branches of the first intercostal nerve.

Ossification

The second rib is ossified from a primary centre for the shaft, which appears near the angle, late in the second month. The secondary centres for the head and articular and non-articular parts of the tubercle appear about puberty, uniting to the shaft soon after the age of 20 years.

Tenth, eleventh and twelfth ribs

The tenth rib has a single facet on its head that may articulate with the intervertebral disc above, in addition to the upper border of the tenth thoracic vertebra near its pedicle. The ninth and tenth ribs are usually united anteriorly by a fibrous joint. However, the tenth rib may be free, in which case it is pointed like the eleventh and twelfth ribs.

The eleventh and twelfth ribs each have one large, articular facet on the head, but no neck or tubercle. Their pointed anterior ends are tipped with cartilage. The eleventh rib has a slight angle and shallow costal groove. The twelfth rib has neither, is much shorter and slopes cranially at its vertebral end. The internal surfaces of both ribs face slightly upwards, more so in the twelfth.

Numerous muscles and ligaments are attached to the twelfth rib (Fig. 54.9). Quadratus lumborum and its anterior covering layer of thoracolumbar fascia are attached to the lower part of its anterior surface in its medial one-half to two-thirds; the upper part is related to the costodiaphragmatic pleural recess. The internal intercostal muscle (medially) and the diaphragm (laterally) are attached at or near the upper border. The lower border gives attachment to the middle lamella of the thoracolumbar fascia and, lateral to quadratus lumborum, to the lateral arcuate ligament and posterior lamella of the thoracolumbar fascia. The lumbocostal ligament is attached posteriorly, close to the head, connecting it to the first lumbar transverse process. The lowest levator costae, longissimus thoracis and iliocostalis are attached to the medial half of the external surface, and serratus posterior inferior, latissimus dorsi and external oblique are attached to its lateral half. The external intercostal muscle is attached along the upper border. These attachments vary: those of the internal intercostal, levator costae and erector spinae merge and those of latissimus dorsi, diaphragm and external oblique may reach the costal cartilage. The lower limit of the
pleural sac crosses in front of the rib, approximately at the point where it is crossed by the lateral border of iliocostalis. Its lateral end is usually below the line of costodiaphragmatic pleural reflection and is therefore not covered by pleura.

**Vascular supply and innervation**

The tenth and eleventh ribs are supplied by the posterior intercostal artery and branches from the musculophrenic artery. The twelfth rib is supplied by the subcostal artery. Venous drainage is via the posterior intercostal and subcostal veins, which in turn drain into the azygos system. There is additional drainage via the anterior
intercostal veins (branches of the musculophrenic vein). The tenth and eleventh ribs are innervated by the corresponding intercostal nerve, and the twelfth rib is innervated by the subcostal nerve.

Ossification

The tenth rib ossifies from a primary centre in the shaft and secondary centres for the head and articular parts of the tubercle. The eleventh and twelfth ribs, without tubercles, have two centres each.

Costal cartilages

Costal cartilages are the persistent, unossified anterior parts of the cartilaginous models in which the ribs develop. They are flat bars of hyaline cartilage that extend from the anterior ends of the ribs, and contribute greatly to thoracic mobility and elasticity (Fig. 54.7). The upper seven pairs join the sternum; the eighth to tenth articulate with the lower border of the cartilage above; the lowest two have free, pointed ends in the abdominal wall. They increase in length from the first to the seventh, and then decrease to the twelfth. They diminish in breadth from first to last, like the intercostal spaces. The costal cartilages are broad at their costal continuity and taper as they pass forward. The first and second are of even breadth and the sixth to eighth enlarge where their margins are in contact. The first descends a little, the second is horizontal and the third ascends slightly; the others are angulated and incline up towards the sternum or cartilage above, a little anterior to their ribs.

Each costal cartilage has two surfaces, borders and ends. The anterior surface is convex, facing anterosuperiorly. The sternoclavicular articular disc, costoclavicular ligament and subclavius are attached to the first costal cartilage. Pectoralis major is attached to the medial aspect of the first six cartilages and the others are covered by the partial attachments of the anterior abdominal muscles. The posterior surface is concave, and really posteroinferior. Sternothyroid is attached to the first cartilage, transversus thoracis is attached to the second to sixth, and transversus abdominis is attached to the lower six. The internal intercostal muscles and external intercostal membranes are attached to the concave superior and convex inferior borders. The inferior borders of the fifth (sometimes), and sixth to ninth cartilages project at points of greatest convexity. Oblong facets on these projections articulate with facets on slight projections from the superior borders of subjacent cartilages. The lateral end of each cartilage is continuous with its rib. The medial end of the first is continuous with the sternum; those of the six succeeding cartilages are round and articulate with shallow costal notches on the lateral margins of the sternum; those of the eighth to tenth are pointed, each connected with the cartilage above; those of the eleventh and twelfth are pointed and free. With the exception of the synarthrosis between the first rib and sternum, all these articulations are synovial.

In old age the costal cartilages tend to ossify superficially, lose their pliability and become brittle.

Rib fractures

Elastic recoil of the ribs which suspend the sternum may explain the rarity of sternal fractures. Despite their pliability, the ribs are much more frequently broken, the middle ribs being the most vulnerable. Because traumatic stress is often the result of
compression of the thorax, the usual site of fracture is just in front of the angle, which is the weakest point of the rib. Direct impact may fracture a rib at any point; the ends of the broken bone may be driven inwards, and potentially may injure thoracic or upper abdominal viscera.
JOINTS

MANUBRIOSTERNAL JOINT

The manubriosternal joint lies between the manubrium and sternal body, and is usually a symphysis. The bony surfaces are covered by hyaline cartilage and connected by a fibrocartilage, which may ossify in the aged. Sometimes, the central part of the disc is absorbed and the joint appears synovial. The manubriosternal joint is connected by a fibrous membrane enveloping the entire bone. In occasional individuals over the age of 30 years, the manubrium is joined to the sternal body by bone, but the intervening cartilage may be only superficially ossified; ossification becomes complete only in the aged. Early synostosis has been attributed to a persistent synchondrosis in place of a symphysis. In the newborn, union is by collagenous and elastic fibres, without chondrocytes.

Movements

The symphysis permits a small range of angulation between the longitudinal axes of the manubrium and body of the sternum, and also limited anteroposterior displacement. A study of these movements in 62 male athletes yielded (standing position) mean values of 162.7° (full inspiration) and 164.7° (full expiration) for the manubriosternal angle: both movements contribute to respiratory excursions of the sternum.
XIPHISTERNAL JOINT

The joint between the xiphoid process and the body of the sternum process is a symphysis. It is usually transformed to a synostosis by the fortieth year, but sometimes remains unchanged even in old age.
STERNOCLAVICULAR JOINT

The sternoclavicular joint is described in Chapter 46.
COSTOVERTEBRAL, STERNOCOSTAL AND INTERCHONDRAL JOINTS

The heads of the ribs articulate with vertebral bodies (costocorporeal joints); their necks and tubercles articulate with transverse processes (costotransverse joints).

Joints of costal heads

Heads of typical ribs articulate with facets (often termed demifacets) on the margins of adjacent thoracic vertebral bodies and with the intervertebral discs between them (Fig. 54.10). The first and tenth to twelfth ribs articulate with a single vertebra by a simple synovial joint. In the others, an intra-articular ligament bisects the joint, producing a double synovial compartment, so the joint is classified as both compound and complex. Often inaccurately described as plane, their articular surfaces are slightly ovoid and the upper and lower synovial articulations are obtusely angled to each other. The ligaments are capsular, radiate and intra-articular.
Fibrous capsules

The fibrous capsule connects the costal head to the circumference of the articular surface formed by an intervertebral disc and the demifacets of two adjacent vertebrae. Some of the upper fibres traverse their intervertebral foramina to blend with the posterior aspects of the intervertebral discs; the posterior fibres are continuous with the costotransverse ligaments.

Radiate ligaments

Radiate ligaments connect the anterior parts of each costal head to the bodies of two vertebrae and their intervening intervertebral disc. Each is attached to the head just beyond its articular surface. Superior fibres ascend to the vertebral body above, inferior to the body below. Intermediate fibres, shortest and least distinct, are horizontal and attached to the disc. The radiate ligament associated with the first rib is attached to the seventh cervical and first thoracic vertebrae. In the joints of the tenth to twelfth ribs, which articulate with single vertebrae, the radiate ligament is attached to the numbered vertebra and the one above.

Intra-articular ligament

The intra-articular ligament is a short, flat band, attached laterally to the crest between the costal articular facets and medially to the intervertebral disc, dividing the joint. The ligament is absent from the first and tenth to twelfth joints.

Costotransverse joints

The facet of a costal tubercle articulates reciprocally with the transverse process of its corresponding vertebra (Fig. 54.11). The eleventh and twelfth ribs lack this articulation. In the upper five or six joints, articular surfaces are reciprocally curved, but below this they are flatter (Fig. 54.12). Their ligaments are capsular, costotransverse, superior and lateral costotransverse, and accessory.
Fig. 54.11 Costovertebral joints, superior aspect.

Fig. 54.12 Section through the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper transverse processes with the less curved facets on the lower transverse processes.

Fibrous capsule

The fibrous capsule is thin and attached to articular peripheries, and has a synovial lining.

Costotransverse ligament

The costotransverse ligament fills the costotransverse foramen between the neck of
the rib and its adjacent corresponding transverse process. Its numerous short fibres extend back from the posterior rough surface on the neck to the anterior surface of the transverse process. A costotransverse ligament is rudimentary or absent in the eleventh and twelfth ribs.

**Superior costotransverse ligament**

The superior costotransverse ligament has anterior and posterior layers. The anterior layer is attached between the crest of the costal neck and lower aspect of the transverse process above, and blends laterally with the internal intercostal membrane; it is crossed by the intercostal vessels and nerve. The posterior layer is attached posteriorly on the costal neck, ascending posteromedially to the transverse process above, and blends laterally with the external intercostal muscle. The first rib has no such ligament. The shaft of the twelfth rib, near its head, is connected to the base of the first lumbar transverse process by a lumbocostal ligament in series with the superior costotransverse ligaments.

**Accessory ligament**

An accessory ligament is usually present. It lies medial to the superior costotransverse ligament, and is separated from it by the dorsal ramus of a thoracic spinal nerve and accompanying vessels. These bands are variable in their attachments, but usually pass from a depression medial to a costal tubercle to the inferior articular process immediately above. Some fibres also pass to the base of the transverse process.

**Lateral costotransverse ligament**

The lateral costotransverse ligament is short, thick and strong and passes obliquely from the apex of the transverse process to the rough non-articular part of the adjacent costal tubercle. The ligaments of upper ribs ascend from their transverse processes, and are shorter and more oblique than those of the lower ribs, which descend.

**Movements**

Costal heads are so firmly tied to vertebral bodies by radiate and intra-articular ligaments that only slight gliding can occur. Strong ligaments binding costal necks and tubercles to transverse processes also limit movements at costotransverse joints to slight gliding, guided by the shape and direction of the articular surfaces (Fig. 54.12). The facets on the tubercles of the upper six ribs are oval and vertically convex, and fit corresponding concavities on the anterior surfaces of transverse processes; consequently, up and down movements of tubercles involve rotation of costal necks about their long axes. The facets on the seventh to tenth tubercles are almost flat, and face down, medially and backwards; their opposing surfaces are on the upper aspects of transverse processes, and so when these tubercles ascend they also move posteromedially. Both sets of joints move simultaneously and in the same directions: the costal neck therefore moves as if at a single joint in which the two articulations form its ends.

In the upper six ribs, the neck moves slightly up and down but its chief movement is one of rotation about its long axis, which means that downward rotation of its anterior aspect is associated with depression, and upward rotation with elevation, of the shaft and anterior end of the rib. In the seventh to tenth ribs, the neck ascends
posteromedially or descends anterolaterally, increasing or diminishing the infrasternal angle respectively; slight rotation accompanies these movements.

**Sternocostal joints**

Costal cartilages articulate with small concavities on the lateral sternal borders (chondrosternal articulations) (Fig. 54.13). Perichondrium and periosteum are continuous. The first sternocostal joint is an unusual variety of synarthrosis, and is often inaccurately called a synchondrosis. The second to seventh costal cartilages articulate by synovial joints, although articular cavities are often absent, particularly in the lower joints. Fibrocartilage covers the articular surfaces and also unites the costal cartilages and the sternum in those joints where cavities are absent. The seventh costosternal joint may be synovial or 'symphysial'. Ligaments involved are capsular, radiate sternocostal, intra-articular and costoxiphoid.

---

**Fig. 54.13** Sternocostal and interchondral joints, anterior aspect.
Fibrous capsules

Fibrous capsules surround the second to seventh sternocostal joints. They are thin, blended with the sternocostal ligaments and are strengthened above and below by fibres that connect the costal cartilages to the sternum.

Radiate sternocostal ligaments

The radiate sternocostal ligaments are broad, thin bands which radiate from the anterior and posterior surfaces of the sternal ends of the costal cartilages of the true ribs to the corresponding sternal surfaces. Their superficial fibres intermingle with adjacent ligaments above and below, with those of the opposite side and with tendinous fibres of pectoralis major; collectively, these tissues form a thick fibrous membrane around the sternum that is more marked inferiorly.

Intra-articular ligaments

Intra-articular ligaments are constant only between the second costal cartilages and sternum. The ligament associated with the second costal cartilage extends from the costal cartilage to the fibrocartilage uniting the manubrium and sternal body and is therefore intra-articular. Occasionally, the third sternal cartilage is connected with the first and second sternal segments by a similar ligament. Fibrocartilaginous strands may occur in the third and lower joints. Articular cavities may be absent at any age.

Costoxiphoid ligaments

Costoxiphoid ligaments connect the anterior and posterior surfaces of the seventh (and sometimes sixth) costal cartilage to the same surfaces of the xiphoid process. They vary in length and breadth, and the posterior is less distinct.

Movements

Slight gliding movements, sufficient for ventilation, occur at sternocostal joints.

Interchondral joints

Contiguous borders of the sixth to ninth costal cartilages articulate by apposition of small oblong facets. Each articulation is enclosed in a thin fibrous capsule, lined by synovial membrane, with lateral and medial interchondral ligaments. Sometimes the fifth cartilage, and less commonly the ninth cartilage, articulate at their inferior borders with adjoining cartilages; this connection is usually effected by ligamentous fibres. Articulation between the ninth and tenth cartilages is never synovial and sometimes absent.

Costochondral junctions

Artificially separated from its rib, a costal cartilage has a rounded end that fits a reciprocal depression in the rib. Periosteum and perichondrium are continuous across the costochondral junctions, and the collagen of the osseous and cartilaginous matrices blend. No movement occurs at costochondral junctions.
MUSCLES

The intrinsic muscles of the chest wall are the intercostals, subcostales, transversus thoracis, levatores costarum and serratus posterior. Scapular muscles and muscles connecting the upper limb, chest wall and vertebrae, i.e. trapezius, latissimus dorsi, rhomboids major and minor, levator scapulae, pectorales major and minor, subclavius, supra- and infraspinatus, teres major and teres minor, are described in detail in Chapter 46.

INTRINSIC CHEST WALL MUSCLES

Intercostal muscles

The intercostal muscles are thin multiple layers of muscular and tendinous fibres that occupy the intercostal spaces; their names are derived from their spatial relationship, i.e. the external, internal and innermost intercostals (Fig. 54.14).
External intercostals

Eleven pairs of external intercostals extend from the tubercles of the ribs, where they blend with the posterior fibres of the superior costotransverse ligaments, almost to the costal cartilages, where each continues forwards to the sternum as an aponeurotic layer, the external intercostal membrane. Each muscle passes from the lower border of one rib to the upper border of the rib below: their fibres are directed obliquely downwards and laterally at the back of the thorax, and downwards, forwards and medially at the front. In the upper two or three spaces, they do not quite reach the ends of the rib, and in the lower two spaces they extend to the free ends of the costal cartilages. The external intercostals are thicker than the internal intercostals.

Innervation
External intercostals are supplied by the adjacent intercostal nerves.

Action

External intercostals are believed to act with the internal intercostals (see Ch. 58).

**Internal intercostals**

Eleven pairs of internal intercostals begin anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the 'false' ribs. Their greatest thickness lies in this intercartilaginous or parasternal part. They continue back as far as the posterior costal angles, where each is replaced by an aponeurotic layer, the internal intercostal membrane, that is continuous posteriorly with the anterior fibres of a superior costotransverse ligament, and anteriorly with the fascia between the internal and external intercostal muscles. Each muscle descends from the floor of a costal groove and adjacent costal cartilage, and inserts into the upper border of the rib below: their fibres are directed obliquely, nearly at right angles to those of the external intercostal muscles.

Innervation

Internal intercostals are supplied by the adjacent intercostal nerves.

Action

Internal intercostals are believed to act with the external intercostals (see Ch. 58).

**Innermost intercostals**

The innermost intercostals were once regarded as internal laminae of the internal intercostal muscles, and fibres in the two layers do coincide in direction. Each muscle is attached to the internal aspects of two adjoining ribs. They are insignificant, and sometimes absent, at highest thoracic levels, but become progressively more substantial below this, typically extending through the middle two quarters of the lower intercostal spaces. Posteriorly, the innermost intercostals, in those spaces where they are well developed, may come together with the corresponding subcostales. The innermost intercostals are related internally to the endothoracic fascia and parietal pleura, and externally to the intercostal nerves and vessels.

Innervation

Innermost intercostals are supplied by the adjacent intercostal nerves.

Action

Innermost intercostals are believed to act with the internal intercostals (see Ch. 58).

**Subcostales**

Subcostales consist of muscular and aponeurotic fasciculi, and are usually well developed only in the lower part of the thorax. Each descends from the internal surface of one rib, near its angle, to the internal surface of the second or third rib below. Their fibres run parallel to those of the internal intercostals and, like the
innermost intercostals, they lie between the intercostal vessels and nerves and the pleura.

Innervation

Subcostales are supplied by the adjacent intercostal nerves.

Action

Subcostales depress the ribs.

Transversus thoracis

Transversus thoracis (triangularis sternalis, sternocostalis) spreads over the internal surface of the anterior thoracic wall (Fig. 54.14). It arises from the lower one-third of the posterior surface of the sternum, the xiphoid process and the costal cartilages of the lower three or four true ribs near their sternal ends. The fibres diverge and ascend laterally as slips that pass into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth and sixth ribs. The lowest fibres are horizontal, and are contiguous with the highest fibres of transversus abdominis, the intermediate fibres are oblique, and the highest are almost vertical. Transversus thoracis varies in its attachments, not only between individuals but even on opposite sides of the same individual. Like the innermost intercostals and subcostales, transversus thoracis separates the intercostal nerves from the pleura.

Innervation

Transversus thoracis is supplied by the adjacent intercostal nerves.

Action

Transversus thoracis draws down the costal cartilages to which it is attached.

Levatores costarum

Levatores costarum are strong bundles, 12 on each side, that arise from the tips of the transverse processes of the seventh cervical and first to eleventh thoracic vertebrae. They pass obliquely downwards and laterally, parallel with the posterior borders of the external intercostals. Each is attached to the upper edge and external surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (levatores costarum breves). Each of the four lower muscles divides into two fasciculi: one is attached as already described, and the other descends to the second rib below its origin (levatores costarum longi).

Innervation

Levatores costarum are supplied by the lateral branches of the dorsal rami of the corresponding thoracic spinal nerves.

Action

Levatores costarum elevate the ribs, but their importance in ventilation is disputed. They are also said to act from their costal attachments as rotators and lateral flexors.
of the vertebral column.

**Serratus posterior**

**Serratus posterior superior**

Serratus posterior superior (Fig. 54.15) is a thin quadrilateral muscle, external to the upper posterior part of the thorax. It arises by a thin aponeurosis from the lower part of the nuchal ligament, the spines of the seventh cervical and upper two or three thoracic vertebrae and their supraspinous ligaments. It descends laterally, and ends in four digitations attached to the upper borders and external surfaces of the second, third, fourth and fifth ribs, just lateral to their angles. It is superficial to the thoracic part of the thoracolumbar fascia and deep to the rhomboids. The number of digitations can vary from three to six, and the muscle may even be absent.

![Fig. 54.15 Superficial (extrinsic) muscles of the back.](image)
Innervation

Serratus posterior superior is innervated by the second, third, fourth and fifth intercostal nerves.

Action

The attachments of serratus posterior superior clearly indicate that it could elevate the ribs: its role in man is uncertain.

Serratus posterior inferior

Serratus posterior inferior is a thin, irregularly quadrilateral muscle at the junction of the thoracic and lumbar regions. It arises from the spines of the lower two thoracic and upper two or three lumbar vertebrae and their supraspinous ligaments by a thin aponeurosis that blends with the lumbar part of the thoracolumbar fascia. It ascends laterally, and its four digitations pass into the inferior borders and outer surfaces of the lower four ribs, a little lateral to their angles. There may be fewer digitations and in rare cases the entire muscle may be absent.

Innervation

Serratus posterior inferior is innervated by ventral rami of the ninth, tenth, eleventh and twelfth thoracic spinal nerves.

Action

Serratus posterior inferior draws the lower ribs downwards and backwards, although possibly not in ventilation.

Mechanism of thoracic cage movement

Breathing involves changing the thoracic volume by altering the vertical, transverse and anteroposterior dimensions of the thorax (see Ch. 58). The diaphragm is the key muscle in this process. Its muscle fibres descend from their relatively ‘high’ anterior sternocostal attachments steeply to the central tendon and obliquely to their complex ‘low’ posterior attachments (see Fig. 58.1). The central tendon is fixed: when the diaphragm contracts, it allows the lower ribcage to move inferiorly and anteriorly without any change to the curvature of the diaphragm. The intercostal muscles maintain the rigidity of the chest wall. The external and internal intercostals, transversus thoracis, subcostales, levatores costarum, serratus posterior superior and serratus posterior inferior can elevate or depress the ribs, and hence can act as accessory muscles of ventilation.
Muscles of the thoracic wall receive their blood supply from the internal thoracic artery, either directly or via the musculophrenic artery, the superior intercostal artery, descending thoracic aorta, and the subcostal and superior thoracic arteries. Additional contributions come from vessels that supply the proximal muscles of the upper limb, namely the suprascapular, superficial cervical, thoracoacromial, lateral thoracic and subscapular arteries.

**Internal thoracic artery**

The internal thoracic artery arises inferiorly from the first part of the subclavian artery, approximately 2 cm above the sternal end of the clavicle, opposite the root of the thyrocervical trunk (see Figs 53.2, 53.3). It descends behind the first six costal cartilages 1 cm from the lateral sternal border and divides at the level of the sixth intercostal space into musculophrenic and superior epigastric branches.

**Relations**

At first, the internal thoracic artery descends anteromedially behind the sternal end of the clavicle, the internal jugular and brachiocephalic veins and the first costal cartilage. As it enters the thorax, the phrenic nerve crosses it obliquely from its lateral side, usually in front. The artery then descends almost vertically to its bifurcation, lying behind pectoralis major, the first six costal cartilages, external intercostal membranes, internal intercostals and terminations of the upper six intercostal nerves. It is separated from the pleura, down to the second or third cartilage, by a strong layer of fascia, and below this by transversus thoracis. The artery is accompanied by a chain of lymph nodes and by venae comitantes that unite at about the third costal cartilage into a single vein medial to the artery. Its intermediate branches are sternal, anterior intercostal and perforating.

**Sternal branches**

Sternal branches are distributed to transversus thoracis, the periosteum of the posterior sternal surface and the sternal red bone marrow. These branches, together with small branches of the pericardiocaphrenic artery, anastomose with branches of the posterior intercostal and bronchial arteries to form a subpleural mediastinal plexus.

**Anterior intercostal branches**

Anterior intercostal arteries are distributed to the upper six intercostal spaces. They pass laterally along the borders of the space and anastomose with the posterior intercostal arteries and their collateral branches. The anterior intercostals usually arise from the internal thoracic artery as single vessels that promptly divide into two branches, one passing to the superior, and one to the inferior, part of each intercostal space. Occasionally, one branch passes to the space above, and one to the space below. (The anterior intercostals may sometimes arise as two separate branches from the internal thoracic artery.) The arteries lie at first between the pleura and the internal intercostals, then between the innermost and the internal intercostals. They supply the intercostal muscles and send branches through them to the pectoral muscles, breast...
and skin.

Perforating branches

Perforating branches traverse the upper five or six intercostal spaces with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce and supply pectoralis major, and then curve laterally to become direct cutaneous vessels that supply the skin. These cutaneous vessels provide the anatomical basis for surgically raising a skin flap in this region, the deltopectoral flap, that is used for reconstructing areas of missing tissue in the head and neck. The second to fourth branches supply the breast, and become enlarged during lactation.

Musculophrenic artery

The musculophrenic artery passes inferolaterally behind the seventh to ninth costal cartilages, traverses the diaphragm near the ninth, and ends near the last intercostal space. It anastomoses with the inferior phrenic and lower two posterior intercostal arteries and ascending branches of the deep circumflex iliac arteries. Two anterior intercostal arteries branch from it for each of the seventh to ninth intercostal spaces, and are distributed similarly to their counterparts in the higher spaces. The musculophrenic artery also supplies the lower part of the pericardium and the abdominal muscles.

Superior intercostal artery

The superior intercostal artery arises from the costocervical trunk. It descends between the pleura and the necks of the first and second ribs and anastomoses with the third posterior intercostal artery. Crossing the neck of the first rib, it lies medial to the ventral branch of the first thoracic spinal nerve, which it crosses at a lower level, and lateral to the stellate ganglion. In the first space it gives off the first posterior intercostal artery, which has a similar distribution to the lower posterior intercostal arteries. It descends to become the second posterior intercostal artery, usually joining a branch from the third. The artery is not constant, and is more common on the right; when absent, it is replaced by a direct branch from the aorta.

Posterior intercostal arteries

There are usually nine pairs of posterior intercostal arteries (Fig. 54.16). They arise from the posterior aspect of the descending thoracic aorta and are distributed to the lower nine intercostal spaces. Right posterior intercostal arteries are longer, because the aorta deviates to the left: they cross the vertebral bodies behind the oesophagus, thoracic duct and azygos vein, right lung and pleura. Left posterior intercostal arteries turn backwards on the vertebral bodies in contact with the left lung and pleura; the upper two are crossed by the left superior intercostal vein, and the lower by the hemiazygos and accessory hemiazygos veins. The further course of the arteries is the same on both sides. The sympathetic trunk lies anterior to all of the arteries, and the splanchnic nerves descend in front of the lower arteries.
Each artery crosses its intercostal space obliquely towards the angle of the rib above and continues forward in its costal groove. At first between the pleura and internal intercostal membrane as far as the costal angle, it passes between the internal intercostal and innermost intercostal muscles (Fig. 54.17), anastomosing with an anterior intercostal branch from either the internal thoracic or musculophrenic artery. Each artery has a vein above and a nerve below, except in the upper spaces, where the nerve at first lies above the artery. The third posterior intercostal artery anastomoses with the superior intercostal artery and may provide the major supply to the second space. The lower two arteries continue anteriorly into the abdominal wall, where they anastomose with the subcostal, superior epigastric and lumbar arteries. Each posterior intercostal artery has dorsal, collateral, muscular and cutaneous branches.
Dorsal branch

Each dorsal branch runs dorsally between the necks of adjoining ribs; a vertebral body and superior costotransverse ligament lie medial and lateral, respectively. Each dorsal branch gives off a spinal branch which enters the vertebral canal via the intervertebral foramen and supplies the vertebrae, spinal cord and meninges, and anastomoses with the spinal arteries above and below and with its contralateral fellow. It then divides into a medial and a lateral dorsal musculocutaneous branch (occasionally these arise separately from the posterior intercostal artery rather than...
from a common trunk). The medial branch crosses a transverse process with the medial dorsal branch of a thoracic spinal nerve to supply spinalis and longissimus thoracis and an area of overlying skin. The lateral branch supplies longissimus thoracis and iliocostalis, and the medial aspects of latissimus dorsi and trapezius, in addition to an area of overlying skin.

Collateral intercostal branch

A collateral intercostal branch arises near the costal angle and descends to the upper border of the subjacent rib, along which it courses to anastomose with an anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches

Muscular branches supply intercostal and pectoral muscles and serratus anterior, and anastomose with the superior and lateral thoracic branches of the axillary artery. Lateral cutaneous branches accompany the same branches of the thoracic spinal nerves. Mammary branches from the vessels in the second to fourth spaces supply the pectoral muscles, breast tissue and skin: they enlarge during lactation.

Lateral cutaneous branch

The lateral cutaneous branch is given off in the posterior part of the intercostal space and travels anteriorly for a few centimetres with an accompanying vein and the lateral cutaneous branch of the equivalent intercostal nerve. This neurovascular bundle pierces the intercostal muscles and emerges lower down between the interdigitations of serratus anterior and external oblique. It divides into anterior and posterior rami, which contribute to the blood supply of the skin of the lateral trunk; these vessels are less significant in the upper three intercostal spaces.

Unnamed branches

Other unnamed branches supply tissues of the thoracic wall, e.g. costal periosteum, bone and bone marrow of the ribs, tissues of synovial and synarthrodial joints and the parietal pleura.
VEINS

Internal thoracic veins

The internal thoracic veins are venae comitantes of the inferior half of the internal thoracic artery. Near the third costal cartilages, the veins unite and ascend medial to the artery to end in their appropriate brachiocephalic vein (see Fig. 28.14). Tributaries correspond to branches of the artery, and include a pericardiacophrenic vein. The internal thoracic veins have several valves.

Left superior intercostal vein

The left superior intercostal vein drains the second and third (sometimes fourth) left posterior intercostal veins. It ascends obliquely forwards across the left aspect of the aortic arch, lateral to the left vagus and medial to the left phrenic nerve, to open into the left brachiocephalic vein (see Fig. 28.14). It usually receives the left bronchial veins, sometimes the left pericardiacophrenic vein, and connects inferiorly with the accessory hemiazygos vein.

Posterior intercostal veins

The posterior intercostal veins accompany their arteries in 11 pairs. Approaching the vertebral column, each vein receives a posterior tributary that returns blood from the dorsal muscles and skin and the vertebral venous plexuses (see Fig. 55.4A,B). On both sides, the first posterior intercostal vein ascends anterior to the neck of the first rib, arching forward above the pleural dome to end in the ipsilateral brachiocephalic or vertebral vein. On the right side, the second, third and often fourth veins form a right superior intercostal vein that joins the arch of the azygos vein. Veins from the lower spaces drain directly to the azygos. On the left side, the second, third and sometimes fourth veins form a left superior intercostal vein. Veins from the fourth or fifth to eighth intercostal spaces end in the accessory hemiazygos vein, and veins from the ninth to the eleventh intercostal spaces end in the hemiazygos vein.

Posterior intercostal veins are so called to distinguish them from small anterior intercostal veins, which are tributaries of the internal thoracic and musculophrenic veins.
LYMPHATIC DRAINAGE

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Fig. 54.19). Those superficial to trapezius and latissimus dorsi unite to form 10 or 12 trunks which end in the subscapular nodes. Those in the pectoral region, including vessels from the skin covering the periphery of the breast and its subareolar plexus, run back, collecting those superficial to serratus anterior, to reach the pectoral nodes. Vessels near the lateral sternal margin pass between the costal cartilages to the parasternal nodes, but also anastomose across the sternum. A few vessels from the upper pectoral region ascend over the clavicle to the inferior deep cervical nodes. Lymph from the deeper tissues of the thoracic walls drains mainly to the parasternal, intercostal or diaphragmatic nodes.

Parasternal (internal thoracic) nodes

There are four or five parasternal nodes along each internal thoracic artery, at the anterior ends of the intercostal spaces. They drain afferents from the breast, deeper structures of the supraumbilical anterior abdominal wall, the superior hepatic surface (through a small group of nodes behind the xiphoid process) and deeper parts of the anterior thoracic wall. Their efferents usually unite with those from the tracheobronchial and brachiocephalic nodes to form the bronchomediastinal trunk. The latter may open, on either side, directly into the jugulosubclavian junction or into either great vein near the junction or may join the right subclavian trunk or right lymphatic duct, or the thoracic duct on the left.

Intercostal nodes

Intercostal nodes occupy the intercostal spaces near the heads and necks of the ribs. They receive deep lymph vessels from the posterolateral aspects of the chest and the breast, some of which are interrupted by small lateral intercostal nodes. Efferents of nodes in the lower four to seven spaces unite into a trunk that descends to the abdominal confluence of lymph trunks or to the start of the thoracic duct. Efferents of nodes in the left upper spaces end in the thoracic duct; those of the right upper spaces end in one of the right lymph trunks.

Diaphragmatic nodes

Located on the thoracic surface of the diaphragm, these nodes are arranged in anterior, right and left lateral, and posterior groups.

Anterior group

The anterior group consists of two or three small nodes behind the base of
the xiphoid process, draining the convex hepatic surface, and one or two
nodes on each side near the junction of the seventh rib and cartilage, which
receive anterior lymph vessels from the diaphragm. The anterior group drains
to the parasternal nodes.

**Lateral groups**

The lateral groups each contain two or three nodes, and lie close to the point
where the phrenic nerves enter the diaphragm. On the right, some nodes lie
within the fibrous pericardium anterior to the intrathoracic end of the inferior
vena cava. Their afferents drain the central diaphragm; those on the right
also drain the convex surface of the liver, and their efferents pass to the
posterior mediastinal, parasternal and brachiocephalic nodes.

**Posterior group**

The posterior group consists of a few nodes that lie on the posterior aspect of
the crura and connect with the lateral aortic and posterior mediastinal nodes.

**Lymphatic drainage of deeper tissues**

Collecting vessels of the deeper thoracic tissues include lymphatics that drain
the muscles attached to the ribs. Most end in axillary nodes, and some from
pectoralis major also drain to the parasternal nodes. Intercostal vessels drain
the intercostal muscles and parietal pleura; those from the anterior thoracic
wall and pleura end in the parasternal nodes, and their posterior counterparts
drain to intercostal nodes.

Vessels from the diaphragm form two plexuses, thoracic and abdominal,
which anastomose freely, especially in areas covered by pleurae and
peritoneum respectively. The thoracic plexus unites with lymph vessels
draining the costal and mediastinal pleura. Its efferents are anterior, draining
to the anterior diaphragmatic nodes near the junctions of the seventh ribs
and cartilages; middle, draining to nodes on the oesophagus and around the
end of the inferior vena cava; posterior, draining to nodes around the aorta at
the point where it leaves the thorax. The abdominal plexus anastomoses with
the hepatic lymphatics and peripherally with those of the subperitoneal
tissue. Efferents from its right half end in a group of nodes on the inferior
phrenic artery, or in the right lateral aortic nodes. Those from the left half of
the abdominal diaphragmatic plexus pass to the pre-aortic and lateral aortic
nodes and to nodes near the terminal oesophagus.
INNERVATION OF THE CHEST WALL

THORACIC VENTRAL SPINAL RAMI

There are 12 pairs of thoracic ventral rami. The upper 11 lie between the ribs (intercostal nerves), and the twelfth lies below the last rib (subcostal nerve) (Figs 54.3, 54.18). Each is connected with the adjoining ganglion of the sympathetic trunk by grey and white rami communicantes; the grey ramus joins the nerve proximal to the point at which the white ramus leaves it. Intercostal nerves are distributed primarily to the thoracic and abdominal walls. The first two nerves supply fibres to the upper limb in addition to their thoracic branches, the next four supply only the thoracic wall, and the lower five supply both thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and the gluteal skin. Communicating branches link the intercostal nerves posteriorly in the intercostal spaces, and the lower five nerves communicate freely in the abdominal wall.

First to sixth thoracic ventral rami

The first thoracic ventral ramus divides unequally. A large branch ascends across the neck of the first rib, lateral to the superior intercostal artery, and enters the brachial plexus. The smaller branch is the first intercostal nerve; it runs in the first intercostal space and ends on the front of the chest as the first anterior cutaneous nerve of the thorax. It gives off a lateral cutaneous branch, which pierces the chest wall in front of serratus anterior and supplies the axillary skin; it may communicate with the intercostobrachial nerve and sometimes joins the medial cutaneous nerve of the arm. The first thoracic ramus often receives a connecting ramus from the second, which ascends in front of the neck of the second rib.

The second to sixth thoracic ventral rami pass forwards in their intercostal spaces below the intercostal vessels. Posteriorly they lie between the pleura and external intercostal membranes, but in most of their course they run between the internal intercostals and the subcostales and innermost intercostals. Near the sternum, they cross anterior to the internal thoracic vessels and transversus thoracis, pierce the internal intercostals, the external intercostal membranes and pectoralis major, and end as the anterior cutaneous nerves of the thorax, supplying the skin on the anterior chest wall. The second anterior cutaneous nerve may be connected to the medial supraclavicular nerves of the cervical plexus, and twigs from the sixth intercostal nerve supply abdominal skin in the upper part of the infrasternal angle.

Branches

Numerous slender muscular filaments supply the intercostals, serratus
posterior superior and transversus thoracis. Anteriorly, some cross the costal cartilages from one intercostal space to another.

Each intercostal nerve gives off a collateral and a lateral cutaneous branch before it reaches the angle of the adjoining ribs (Fig. 54.18). The collateral branch follows the inferior border of its space in the same intermuscular place as the main nerve, which it may rejoin before it is distributed as an additional anterior cutaneous nerve. The lateral cutaneous branch accompanies the main nerve a little way and then pierces the intercostal muscles obliquely. With the exception of the lateral cutaneous branches of the first and second intercostal nerves, each divides into anterior and posterior rami that subsequently pierce serratus anterior. Anterior branches run forwards over the border of pectoralis major to supply the overlying skin; those of the fifth and sixth also supply twigs to a variable number of upper digitations of external oblique. Posterior branches run backwards and supply the skin over the scapula and latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is the intercostobrachial nerve (see Fig. 46.30). It crosses the axilla to gain the medial side of the arm and joins a branch of the medial cutaneous nerve of the arm. It then pierces the deep fascia of the arm, and supplies the skin of the upper half of the posterior and medial parts of the arm, communicating with the posterior cutaneous branch of the radial nerve. Its size is in inverse proportion to the size of the medial cutaneous nerve. A second intercostobrachial nerve often branches off from the anterior part of the third lateral cutaneous nerve and sends filaments to the axilla and the medial side of the arm.

Seventh to eleventh thoracic ventral rami

The ventral rami of the seventh to eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall; their further course is described in Chapter 62.

Lesions of the intercostal nerves

Subluxation of the interchondral joints between the lower costal cartilages may trap the intercostal nerves, causing referred abdominal pain. The dorsal cutaneous branch of an intercostal nerve can become entrapped as it penetrates the fascia of erector spinae. This produces an area of numbness, usually with painful paraesthesiae, which extends approximately 10 cm from the midline laterally and 10 cm in length (notalgia paraesthetica); the area between the medial edge of the scapula and the spine is commonly affected. The anterior cutaneous branches of the intercostal nerves can become entrapped as they penetrate the fascia of rectus abdominis, and this produces an area of numbness on the abdomen, usually with painful
paraesthesiae, which extends from the midline laterally 10 or 12 cm (rectus abdominis syndrome).

Twelfth thoracic ventral ramus (subcostal nerve)

The ventral ramus of the twelfth thoracic nerve (subcostal nerve) is larger than the others and gives a communicating branch to the first lumbar ventral ramus (sometimes termed the dorsolumbar nerve). Like the intercostal nerves, it soon gives off a collateral branch and then accompanies the subcostal vessels along the inferior border of the twelfth rib, passing behind the lateral arcuate ligament and kidney and in front of the upper part of quadratus lumborum. It perforates the aponeurosis of the origin of transversus abdominis and passes forwards between that muscle and internal oblique, to be distributed in the same manner as the lower intercostal nerves. The subcostal nerve connects with the iliohypogastric nerve of the lumbar plexus and sends a branch to pyramidalis. Its lateral cutaneous branch pierces the internal and external oblique muscles and supplies the lowest slip of the latter. It usually descends over the iliac crest 5 cm behind the anterior superior iliac spine (see Fig. 61.4) and is distributed to the anterior gluteal skin; some filaments reach as low as the greater trochanter of the femur.
THORACIC DORSAL SPINAL RAMI

Thoracic dorsal rami pass backwards close to the vertebral zygapophysial joints and divide into medial and lateral branches. The medial branch emerges between the joint and the medial edge of the superior costotransverse ligament and intertransverse muscle. The lateral branch runs in the interval between the ligament and the muscle before inclining posteriorly on the medial side of levator costae.

Medial branches of the upper six thoracic dorsal rami pass between and supply semispinalis thoracis and multifidus; they then pierce the rhomboids and trapezius, and reach the skin near the vertebral spines (see Fig. 43.6). Medial branches of the lower six thoracic dorsal rami are distributed mainly to multifidus and longissimus thoracis; occasionally they give filaments to the skin in the median region. Lateral branches increase in size from above downwards. They run through or deep to longissimus thoracis to the interval between it and iliocostalis cervicis, and supply these muscles and levatores costarum; the lower five or six also give off cutaneous branches, which pierce serratus posterior inferior and latissimus dorsi in line with the costal angles (see Fig. 43.6). The lateral branches of a variable number of the upper thoracic rami also supply the skin. The lateral branch of the twelfth sends a filament medially along the iliac crest, then passes down to the skin of the anterior part of the gluteal region.

Medial cutaneous branches of the thoracic dorsal rami descend for some distance close to the vertebral spines before reaching the skin. Lateral branches descend for a considerable distance, which may be as much as the breadth of four ribs, before they become superficial, e.g. the branch of the twelfth thoracic ramus reaches the skin only a little way above the iliac crest.
BREAST

The breasts form a secondary sexual feature of females and are the source of nutrition for the neonate. They are also present in a rudimentary form in males. The breasts are the site of malignant change in as many as one in ten women. For reviews of normal breast structure, consult Ellis et al (1993).

In young adult females, each breast is a rounded eminence lying within the superficial fascia, largely anterior to the upper thorax but spreading laterally to a variable extent (Figs 54.19, 54.20B). Breast shape and size depend upon genetic, racial and dietary factors, and the age, parity and menopausal status of the individual. Breasts may be hemispherical, conical, variably pendulous, piriform or thin and flattened. In the adult female, the base of the breast, i.e. its attached surface, extends vertically from the second or third to the sixth rib, and in the transverse plane from the sternal edge medially almost to the midaxillary line laterally. The superolateral quadrant is prolonged towards the axilla along the inferolateral edge of pectoralis major, from which it projects a little, and may extend through the deep fascia up to the apex of the axilla (the axillary tail of Spence). The trunk superficial fascial system splits to enclose the breast to form the anterior and posterior lamellae. Posterior extensions of the superficial fascial system connect the breast to the pectoralis fascia, part of the deep fascial system. The inframammary crease is a zone of adherence of the superficial fascial system to the underlying chest wall at the inferior crescent of the breast.
The breast lies upon the deep pectoral fascia, which in turn overlies pectoralis major and serratus anterior superiorly and external oblique and its aponeurosis (as the latter forms the anterior wall of the sheath of rectus abdominis) inferiorly. Between the breast and the deep fascia the loose connective tissue in the ‘submammary space’ allows the breast some degree of movement on the deep pectoral fascia. Advanced mammary carcinoma may, by invasion, cause tethering or fixation of the breast to the underlying musculature. Occasionally, small projections of glandular tissue may pass through the deep fascia into the underlying muscle in normal subjects.

The nipple projects from the centre of the breast anteriorly (Fig. 54.20C,D). Its shape and projection varies from cylindrical and rounded at the top, to hemispherical, to flattened, depending on nervous, hormonal, developmental and other factors. The level of the nipple varies widely. In females, its site is dependent on the size and shape of the breasts, but it overlies the fourth intercostal space in most young women. In the male, the nipple is usually sited in the fourth intercostal space in the midclavicular line. In the young adult of either sex, the nipples are usually positioned 20–23 cm from the suprasternal notch in the midclavicular line and 20–23 cm apart in
the horizontal plane. With increasing age and parity, female breasts adopt a more ptotic shape and the nipple position drops either to the level of the inframammary crease or lies below this surface landmark. In the nulliparous, it is pink, light brown or darker, depending on the general melanization of the body. Occasionally, the nipple may not evert during prenatal development, in which case it remains permanently retracted and so causes difficulty in suckling.

**NIPPLE AND AREOLA**

The skin covering the nipple and the surrounding areola (the disc of skin that circles the base of the nipple) has a convoluted surface (Fig. 54.20C). It contains numerous sweat and sebaceous glands which open directly onto the skin surface. The oily secretion of these specialized sebaceous glands acts as a protective lubricant and facilitates latching of the neonate during lactation: the glands are often visible in parous women, arranged circumferentially as small elevations, Montgomery’s tubercles, around the areola close to the margin. Other areolar glands, which are intermediate in structure between mammary and sweat glands, become enlarged in pregnancy and lactation as subcutaneous tubercles. The sebaceous glands of the areola usually lack hair follicles. The skin of the nipple and areola is rich in melanocytes and is therefore typically darker than the skin covering the remainder of the breast: further darkening occurs during the second month of pregnancy, and subsequently persists to a variable degree.
SOFT TISSUE

The breasts are composed of lobes which contain a network of glandular tissue consisting of branching ducts and terminal secretory lobules in a connective tissue stroma (see Fig. 54.26A). The terminal duct lobular unit is the functional milk secretory component of the breast and pathologically gives rise to primary malignant lesions within the breast. Although the lobes are usually described as discrete territories, they intertwine in three dimensions and merge at their edges; they cannot be distinguished during surgery. The connective tissue stroma that surrounds the lobules is dense and fibrocollagenous, whereas intralobular connective tissue has a loose texture that allows the rapid expansion of secretory tissue during pregnancy (see Fig. 54.26B). Fibrous strands or sheets consisting of condensations of connective tissue extend between the layer of deep fascia that covers the muscles of the anterior chest wall and the dermis. These suspensory ligaments (of Astley Cooper) are often well developed in the upper part of the breast and support the breast tissue, helping to maintain its non-ptotic form. Elsewhere in the normal breast, fibrous tissue surrounds the glandular components and extends to the skin and nipple, assisting the mechanical coherence of the gland. The interlobar stroma contains variable amounts of adipose tissue which is responsible for much of the increase in breast size at puberty.
Fig. 54.26  Microstructure of breast epithelium. A. Note that the myoepithelial process is actually about half the relative size shown in the lower diagram. B. The peripheral part of a lactating breast lobule enclosed by a connective tissue septum (left). The alveoli are distended by milk secretion. Milk protein appears as eosinophilic material in the lumen and milk fat as pale cytoplasmic vacuoles in the flattened alveolar epithelium. Intralobular connective tissue between the alveoli contains a prominent lymphocytic infiltration, including plasma cells secreting IgA.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The breasts are supplied by branches of the axillary artery, the internal thoracic artery, and some intercostal arteries. The axillary artery supplies blood via the superior thoracic artery, the pectoral branches of the thoracoacromial artery, the lateral thoracic artery (via branches which curve around the lateral border of pectoralis major to supply the lateral aspect of the breast) and the subscapular artery. The internal thoracic artery supplies perforating branches to the anteromedial part of the breast. The second to fourth anterior intercostal arteries supply perforating branches more laterally in the anterior thorax: the second perforating artery is usually the largest, and supplies the upper region of the breast, and the nipple, areola and adjacent breast tissue.

Veins

Blood drains from the circular venous plexus around the areola and from the glandular tissue of the breast into the axillary, internal thoracic and intercostal veins via veins that accompany the corresponding arteries. Individual variation is common.

Lymphatic drainage

The lymphatic flow of the breast is of great clinical significance because metastatic dissemination occurs principally by the lymphatic routes. The dominant lymphatic drainage of the breast is derived from the dermal network. The breast lymphatics branch extensively and do not contain valves: lymphatic blockage through tumour occlusion may therefore result in reverse blood flow through the lymphatic channels. The direction of lymphatic flow within the breast parallels the major venous tributaries and enters the regional lymph nodes via the extensive periductal and perilobular network of lymphatic channels. Most of these lymphatics drain into the axillary group of regional lymph nodes either directly or through the retroareolar lymphatic plexus (see Fig. 46.28). Dermal lymphatics also penetrate pectoralis major to join channels that drain the deeper parenchymal tissues, and then follow the vascular channels to terminate in the subclavicular lymph nodes. Lymphatics from the left breast ultimately terminate in the thoracic duct and subsequently the left subclavian vein. On the right, the lymphatics ultimately drain into the right subclavian vein near its junction with the internal jugular vein. Part of the medial side of the right breast drains towards the internal thoracic group of lymph nodes. The internal thoracic chain may drain inferiorly via the superior and inferior epigastric lymphatic routes to the groin. Connecting lymphatics across the midline may provide access of lymphatic flow to the opposite axilla.
Axillary nodes receive more than 75% of the lymph from the breast (Fig. 54.21). There are 20–40 nodes, grouped artificially as pectoral (anterior), subscapular (posterior), central and apical. Surgically, the nodes are described in relation to pectoralis minor. Those lying below pectoralis minor are the low nodes (level 1), those behind the muscle are the middle group (level 2), while the nodes between the upper border of pectoralis minor and the lower border of the clavicle are the upper or apical nodes (level 3). There may be one or two other nodes between pectoralis minor and major; this interpectoral group of nodes are also known as Rotter's nodes. Efferent vessels directly from the breast pass round the anterior axillary border through the axillary fascia to the pectoral lymph nodes; some may pass directly to the subscapular nodes. A few vessels pass from the superior part of the breast to the apical axillary nodes, sometimes interrupted by the infraclavicular nodes or by small, inconstant, interpectoral nodes. Most of the remainder drains to parasternal nodes from the medial and lateral parts of the breast; they accompany perforating branches of the internal thoracic artery. Lymphatic vessels occasionally follow lateral cutaneous branches of the posterior intercostal arteries to the intercostal nodes.

Axillary surgery in breast cancer

Axillary lymph node dissection may be performed because the presence of metastases within axillary lymph nodes has strong prognostic significance and might influence decisions on adjuvant therapy. However, axillary lymph node dissection can lead to chronic postoperative problems such as pain, seroma formation, reduced mobility of the arm, impaired sensation and lymphoedema The vessels and nerves have to be carefully identified at surgery as anatomical landmarks.

Lymphatic drainage in breast cancer and role of sentinel lymph node biopsy

Lymphatic mapping with sentinel lymph node biopsy has become an important technique in the staging of patients with early breast cancer. A radiolabelled colloid is injected into either the subareolar tissue of the index quadrant of the breast or the peritumoural tissue and intradermal tissue overlying the primary breast cancer. At the time of surgery, a vital blue dye is injected after general anaesthesia is established. The combination of radioisotope and dye provides the most accurate means of localizing the sentinel node (Rubio & Klimberg 2001, Tanis et al 2001). The sentinel node represents the first draining node of the axilla and is surgically removed for careful histopathological analysis to detect the presence of metastases. The sentinel node procedure seeks to identify this first draining node, and, if negative for cancer metastases, avoids more radical surgery in women who have no cancer spread, thus reducing morbidity associated with axillary dissection. In women who are found to have metastases to the axillary node, selective treatment to the axilla by completion axillary dissection or
radiotherapy is offered. The majority of sentinel nodes are found in the low axilla within the level I group of nodes but can sometimes be found in higher echelon axillary nodes. This occurs in 5–10% of cases; the nodes are termed skip-metastases. Occasionally, the sentinel node is identified in an extra-axillary position, either within the breast parenchyma in an intramammary lymph node, the internal thoracic lymph node chain, or in the supraclavicular fossa.
INNERVATION

The breast is innervated by anterior and lateral branches of the fourth to sixth intercostal nerves, which carry sensory and sympathetic efferent fibres. The nipple is supplied from the anterior branch of the lateral cutaneous branch of T4 which forms an extensive plexus within the nipple; its sensory fibres terminate close to the epithelium as free endings, Meissner corpuscles and Merkel disc endings. These are essential in signalling suckling to the central nervous system. Secretory activities of the gland are largely controlled by ovarian and hypophysial hormones rather than by efferent motor fibres. The areola has fewer sensory endings.
MICROSTRUCTURE

The microstructure of breast tissue varies with age, time in the menstrual cycle, pregnancy and lactation. The following description relates to the mature, resting breast. For most of their lengths, the ducts are lined by columnar epithelium (Fig. 54.22). In the larger ducts, this is two cells thick, but, in the smaller ones, only a single layer of columnar or cuboidal cells is present. The bases of these cells are in close contact with numerous myoepithelial cells of ectodermal origin, similar to those of certain other glandular epithelia (see Figs 2.3, 54.26A). Myoepithelial cells are so numerous that they form a distinct layer surrounding the ducts and presumptive alveoli and give the epithelium a bilayered appearance.
Lactiferous ducts draining each lobe of the breast pass through the nipple and open onto its tip as 15–20 orifices. Near its orifice, each of these ducts is slightly expanded as a lactiferous sinus, which, in the lactating breast, is
further dilated by the presence of milk. Each lactiferous duct is therefore connected to a system of ducts and lobules, surrounded by connective tissue stroma, collectively forming a lobe of the breast. Lobules consist of the portions of the glands that have secretory potential. Their structure varies according to hormonal status. In the mature resting breast, each lobule consists of a cluster of blind-ended, branched ductules whose termini lack terminal alveoli (acini), which are the sites of milk secretion in the lactating breast (see Fig. 54.26B). The stratified cuboidal lining is replaced by keratinized stratified squamous epithelium, continuous with the epidermis, close to the openings of the lactiferous ducts on the nipple. Shed squames may sometimes block the duct apertures in the non-pregnant breast.

Internally, the nipple is composed mostly of collagenous dense connective tissue and contains numerous elastic fibres which wrinkle the overlying skin. Deep to the nipple and areola, bundles of smooth muscle cells are arranged radially and circumferentially within the connective tissue. Their contraction, induced by cold or tactile stimuli (e.g. in suckling), causes erection of the nipple and wrinkling of the surrounding areola.
BREAST CANCER

Breast cancer is a common disease, particularly in postmenopausal women (see Fentiman 1993). Each year in the United Kingdom, there are approximately 40,000 new cases diagnosed and 14,000 deaths. Male breast cancers make up 1% of all mammary malignancies and may include tissue beyond the areolar boundary.

Breast cancers arise within the epithelia of lobules or ducts. As they increase in size and infiltrate the stroma they often lead to a fibrous tissue reaction. Breast lumps may be classified as benign or malignant masses. Malignant breast lumps may have the clinical signs of infiltrating adjacent structures, leading to a hard and irregular mass with skin-tethering, muscle fixation, skin infiltration or oedema of the overlying skin (peau d'orange). Standard radiological imaging investigations of the breast include mammography and ultrasonography. Mammography is useful in detecting the presence of malignant masses as a stellate opacity with architectural distortion of the surrounding parenchyma. Early stages of preinvasive breast cancer, ductal cancer in situ, may appear as microcalcification on the mammogram. An ultrasound scan of the breast is helpful to distinguish solid from cystic (or fluid-filled) masses, and can also aid in the distinction of breast cancer from benign lumps by the different attenuation characteristics of the ultrasound waves and blood flow patterns. Magnetic resonance imaging is also useful in diagnosis, particularly in women with younger, more dense breasts, achieving higher sensitivity of breast cancer detection but with lower specificity. A cytological diagnosis of a breast lump can be achieved using fine needle aspiration (FNA) to evaluate the cellular component of a lump. FNA is also useful to drain symptomatic breast cysts. A wide bore needle biopsy is a procedure performed under local anaesthetic to obtain several pieces of specimen for a histological diagnosis with the tissue architecture maintained. This permits distinction between in situ and invasive cancer and provides an indication of tumour subtype by evaluation of the pathological characteristics. Vacuum-assisted mamtotome biopsies based on the wide bore needle enables some benign and indeterminate lesions to be excised for full histological analysis and in some patients can avoid the need for conventional open surgery.

If a breast lump has to be surgically removed, the incision should be based, whenever possible, in the relaxed skin tension lines, for the best cosmetic results. In women with sizeable malignant lesions where breast conservation surgery is to be attempted, the skin incision should be planned with consideration of the possible requirement of the need for a subsequent mastectomy if the margins of excision are incompletely excised by pathological criteria. Most women with single breast cancers up to 4 cm in diameter are treated by breast conservation rather than mastectomy. This is
a combination of surgery (tumour excision and axillary lymph node sampling or clearance) together with external beam radiotherapy. Patients with larger tumours are treated by modified radical mastectomy with axillary lymph node clearance. During axillary dissection to clear the axillary lymph nodes, the nerve to serratus anterior, the thoracodorsal vessels, the nerve to latissimus dorsi, and the medial and lateral pectoral nerves are all identified and carefully preserved. The boundaries of the axillary dissection are the nerve to serratus anterior medially, the thoracodorsal pedicle laterally and the axillary vein superiorly (see Fig. 46.30). The posterior limit of the dissection is the ventral surface of subscapularis. The superomedial limit of a level I axillary dissection extends to the lateral border of pectoralis minor at the apex of the axilla, a level II dissection extends to the medial border of pectoralis minor, and a level III dissection extends beyond the medial border until it reaches the point where the axilla is limited by the first rib (the latter is easily distinguished by its flat lateral surface, easily palpable at surgery). Failure to preserve the nerve to serratus anterior will result in winging of the scapula. The intercostobrachial nerve is often sacrificed in an axillary lymph node clearance operation, and this may result in anaesthesia of a narrow strip of sensation in the upper medial border of the arm.

**Reconstructive surgery for breast cancer disease**

Breast reconstruction may be performed at the time of mastectomy for breast cancer, or at a later stage (Serletti & Moran 2000). During a mastectomy where an immediate breast reconstruction is planned, the glandular breast tissue is removed either through a conventional mastectomy skin incision or in association with preservation of the native breast skin, a form of mastectomy termed a skin-sparing mastectomy. Patient selection is important to minimize risks of breast cancer recurrence in the skin of the reconstructed breast mound or associated lymph nodes. In an implant-based immediate breast reconstruction, a tissue expander is placed beneath the submusculofascial plane consisting of pectoralis major, in continuity laterally under serratus anterior with the intervening fascia, and the abdominal fascia inferiorly. The lower fibres of the attachment of pectoralis major to the sixth rib need to be detached, otherwise the implant will be placed too high on the chest wall. The tissue expander has to stretch the potential space below this musculofascial plane to match the space created by the removed breast beneath the subcutaneous plane and the deep fascia overlying pectoralis major. The tissue expander is subsequently replaced by a silicone or saline breast implant.

The skin and volume component of the breast can also be replaced by the latissimus dorsi musculocutaneous flap with or without an underlying silicone or saline breast implant. Latissimus dorsi and an overlying paddle of skin is raised on its dominant vascular pedicle, namely the thoracodorsal artery and vein, which enter the muscle on its deep surface and send perforating
branches through the muscle to the overlying skin. The flap is transferred in an arc from the back to the front of the chest and fashioned to make a new breast. An implant is usually required to provide additional volume replacement, in which case it is placed beneath the flap. The donor defect on the back is directly sutured and there is minimal functional disability following transfer of latissimus dorsi. In suitable women, subcutaneous fat harvested in conjunction with the latissimus dorsi muscle may contain sufficient material to avoid the need for an implant as an autologous tissue breast reconstruction.

The skin and volume component of the breast can be replaced by a pedicled transverse rectus abdominis musculocutaneous flap (TRAM flap). In a pedicled TRAM flap, rectus abdominis and a transverse ellipse of skin from the lower abdomen are raised on the superior epigastric artery, which enters the deep surface of the muscle below the costal cartilage. Women suitable for an abdominal-based procedure have a sufficient abdominal panniculus to form the donor tissue in order to recreate the breast mound without an implant. Microvascular surgical techniques now permit the free transfer of the lower abdominal panniculus skin and subcutaneous fat based upon the cutaneous supply of the deep inferior epigastric artery with minimal disruption to rectus abdominis. Cutaneous perforators near the level of the umbilicus pass to the skin in two rows (a medial and a lateral row). If the superior epigastric artery is used as the pedicle for the flap, the deep inferior epigastric artery is ligated and the flap is swung on the pedicle and tunnelled up into the chest where it is fashioned into a new breast. If the deep inferior epigastric artery is used as the pedicle, the superficial epigastric artery is divided and the flap is transferred as a free flap; the deep inferior epigastric artery and vein are anastomosed to recipient vessels either in the chest (usually the internal thoracic vessels, accessed by removing the third costal cartilage) or to the dominant anterior intercostal perforator in the second (or third) intercostal space. A deep inferior epigastric artery perforator flap (DIEP flap) can be raised by dissecting a single cutaneous perforator through rectus abdominis to its origin from the deep inferior epigastric artery, a procedure that obviates the need to sacrifice the muscle.

The advantage of the TRAM flap over the latissimus dorsi flap is that there is sufficient volume to reconstruct even a large breast without the need for an implant. The donor defect in the abdominal wall is sutured directly; where the muscle has been harvested in the pedicled TRAM flap, a mesh may be incorporated into the repair of the rectus sheath to reduce the potential risk of muscle weakness caused by surgical disruption of rectus abdominis, which could produce a bulge of the abdominal contents or a hernia.
DEVELOPMENT

The epithelial/mesenchymal interactions that will give rise to the glandular tissue of the breast, in both sexes, can first be seen at about the fifth or sixth week, when two ventral bands of thickened ectoderm, the mammary ridges or milk lines, extend from the axilla to the inguinal region. Usually, invagination of the thoracic mammary bud occurs by day 49, and the remaining mammary line involutes.

The thoracic ectodermal ingrowths branch into 15–20 solid buds of ectoderm which will become the lactiferous ducts and their associated lobes of alveoli in the fully formed gland. They are surrounded by somatopleuric mesenchyme which forms the connective tissue, fat and vasculature which is invaded by the mammary nerves. Continued cell proliferation, elongation and further branching produces the alveoli and defines the duct system. Nipple formation begins at day 56, primitive ducts (mammary sprouts) develop at 84 days and canalization occurs at about the 150th day. During the last 2 months of gestation the ducts become canalized; the epidermis at the point of original development of the gland forms a small mammary pit, into which the lactiferous tubules open (Fig. 54.23). Perinatally the nipple is formed by mesenchymal proliferation. Should this process fail, the ducts open into shallow pits. Rarely, the nipple may not develop (athelia), a phenomenon that occurs more commonly in accessory breast tissue.
At birth the breasts have reached a similar developmental stage in both sexes: the combination of fetal prolactin and maternal oestrogen may give rise to transient hyperplasia and secretion of ‘witch’s milk’. In males, the breasts normally remain undeveloped, whereas in females at puberty, in late pregnancy and during the period of lactation, they undergo further, hormone-dependent, developmental changes. The female breast is a unique organ in that it remains in a rudimentary (i.e. fetal) form until puberty, at which time its development continues under the influence of sex hormones. The adult form is reached in late adolescence, i.e. the breast is then able to function as a milk-producing organ. At menopause, the breast involutes into a predominantly fatty organ with minimal glandular parenchyma.

**Accessory breast tissue and nipples**

Polymastia (supernumerary breasts) and polythelia (supernumerary nipples) may develop in males and females anywhere along the length of the mammary ridges (milk lines; Fig. 54.24). Conversely, breast tissue may not develop at all (amastia) or there may be nipple development but no breast tissue (amazia). Supernumerary breast development occurs in most cases in the thoracic region, just inferior to the normal breast (90%), but may also occur in the axillary (5%) and abdominal regions (5%). Polythelia occurs along the same mammary line but no underlying glandular tissue develops. About 1% of the female population has this condition, but it is more common in males, where the accessory nipple may be mistaken for a mole.
Congenital inversion of nipple

Congenital inversion of the nipples occurs in about 3% of the female population. The condition is almost always bilateral. The majority of the cases are umbilicated, i.e. the nipple can be easily pulled forward from its depressed position underneath the areolar surface. The condition is thought to be due to failure of proliferation of the mesenchymal tissue, which fails to push the nipple out. The remaining cases are due to invagination of the nipple. Apart from psychological implications, inversion of the nipple may cause recurrent mastitis and difficulty with breast feeding. The abnormality may be corrected surgically.
AGE-RELATED CHANGES

Prepuberty

The neonatal breast contains lactiferous ducts but no alveoli. Until puberty, little branching of the ducts occurs, and any slight mammary enlargement reflects the growth of fibrous stroma and fat.

Puberty

In the postpubertal female, the ducts, stimulated by ovarian oestrogens, become branched. The ends of the branches form solid, spheroidal masses of granular polyhedral cells, the potential alveoli. Oestrogens also promote adipocyte differentiation from mesenchymal cells in the interlobar stroma: breast enlargement at puberty is largely a consequence of lipid accumulation by these adipocytes.

From puberty onwards, externally recognizable breast development (thelarche) can be divided into five separate phases (Fig. 54.25): elevation of the breast bud (phase I); glandular subareolar tissue is present and both nipple and breast project from the chest wall as a single mass (phase II); the areola increases in diameter and becomes pigmented, and there is proliferation of palpable breast tissue (phase III); further pigmentation and enlargement occurs in the areola, so that the nipple and areola form a secondary mass anterior to the main part of the breast (phase IV); a smooth contour to the breast develops (phase V).
Changes during the menstrual cycle

Changes occur in the breast tissues in the menstrual cycle. In the follicular phase (days 3–14), the stroma becomes less dense. Various changes including luminal expansion take place in the ducts; there are occasional mitoses but no secretion. In the luteal phase (days 15–28), there is a progressive increase in stromal density and the ducts have an open lumen that contains secretion, associated with flattening of the epithelial cells. Cell proliferation is maximal on day 26 and thereafter the ductal system undergoes reduction; epithelial cell apoptosis is greatest on day 28 of the cycle. There are also changes in blood flow, which are greatest at midcycle, and an increase in the water content of the stroma in the second half of the menstrual cycle.

Postmenopausal

Progressive atrophy of lobules and ducts occurs after the menopause, and there is fatty replacement of glandular breast tissue. A few ducts may remain. The stroma becomes much less cellular and collagenous fibres decrease. The amount of adipose tissue varies widely between individuals, and the breast may return to a condition similar to the prepubertal state.
CHANGES ASSOCIATED WITH PREGNANCY AND LACTATION

Pregnancy

As the output of oestrogen and progesterone produced first by the corpus luteum and later by the placenta rises during pregnancy, the intralobular ductal epithelium proliferates and the cells increase in size: the number and length of the ductal branches therefore increase. Alveoli develop at their termini and expand as their cells and lumina fill with newly synthesized and secreted milk. The myoepithelial cells, which are initially spindle-shaped, become highly branched stellate cells, especially around the alveoli. Adjacent myoepithelial cells intermesh to form a basket-like network around the alveoli and ducts, interposed between the basal lamina and the luminal cells. Their cytoplasm contains actin and myosin filaments and they are contractile. There is a concomitant reduction in adipose tissue in the stroma. The numbers of lymphocytes, including plasma cells, and eosinophils increase greatly. Blood flow through the breast increases.

Secretory activity in the alveolar cells rises progressively in the latter half of pregnancy. In late pregnancy, and for a few days after parturition, their product is different from later milk and is known as colostrum, which is low in lipid but rich in protein and immunoglobulins. Colostrum confers a measure of passive immunity to the neonatal alimentary tract; it also has laxative properties. Proliferation of the glandular breast parenchyma results in an overall increase in breast size through gestation.

Lactation

True milk secretion begins a few days after parturition as a result of a reduction in circulating oestrogen and progesterone, a change which appears to stimulate production of prolactin by the anterior hypophysis.

Milk distends the alveoli so that the cells flatten as secretion increases (Figs 54.20B, 54.26B,C). The alveolar cell cytoplasm accumulates membrane-bound granules of casein and other milk proteins, and these are released from the apical plasma membrane by membrane fusion (merocrine secretion; see Ch. 2). Lipid vacuoles are formed directly in the apical cytoplasm as small lipid droplets which fuse with each other to create large 'milk vacuoles' up to 10 µm across, that frequently protrude from the cell surface. These are released as intact lipid droplets with a thin surround of apical plasma membrane and adjacent cytoplasm (apocrine secretion). On hormonal stimulation by oxytocin, myoepithelial cells contract to expel alveolar secretions into the ductal system in readiness for suckling.

After the onset of lactation there is a gradual reduction in the numbers of lymphocytes and eosinophils in the stroma, although plasma cells continue to
synthesize IgA for secretion into the milk. Alveolar cells take up IgA synthesized by adjacent plasma cells by endocytosis at their basal surfaces and secrete it apically, as dimers complexed to epithelial secretory component.

**Postlactation**

When lactation ceases, which may be as long as 3½ years, or even longer if frequent suckling is maintained, the secretory tissue undergoes some involution, but the ducts and alveoli never return completely to the pre-pregnant state. Two major processes are responsible for the regression of the alveolar–ductal system: a reduction in epithelial cell size and a reduction in cell numbers mediated via apoptosis (see Ch. 1). Gradually the breast tissue reverts to its resting state. If another pregnancy occurs, the resting glandular tissue is reactivated, and the process outlined above recurs. Up to the age of 50 years, increasing amounts of elastic tissue tend to be laid down around vessels and ducts (elastosis), and also in the stroma. Elastosis does not normally continue into later life.
**MALE BREAST**

The male breast remains rudimentary throughout life. It is formed of small ducts (without lobules or alveoli) or solid cellular cords and a little supporting fibroadipose tissue (see Ellis et al 1993). Slight temporary enlargement may occur in the newborn, reflecting the influence of maternal hormones, and again at puberty. The areola is well developed, although limited in area, and the nipple is relatively small. It is usually stated that the ducts do not extend beyond the areola in a male breast, but glandular tissue can be more extensive.

**Gynaecomastia**

Gynaecomastia is a benign proliferation of subareolar breast tissue or excessive growth of breast tissue. It is usually bilateral but may be unilateral, and is commonly associated with pain or tenderness, which is thought to be due to accumulation of fluid in the glandular ducts. Histological changes are fibrosis, followed by hyalinization. It is sometimes due to a biochemical imbalance in the ratio of free oestrogens, androgens and sex hormone-binding globulin. Hence it is commonly seen after antiandrogen therapy for conditions such as prostatic cancer, but other drugs such as spironolactone, cimetidine, anabolic steroids and cannabinoids have been implicated. Gynaecomastia may have a hormonal basis during puberty and senescence, or in liver failure where normal hepatic function is associated with sex steroid hormone metabolism. However, the majority of cases have no known cause and are termed idiopathic gynaecomastia.
SURGICAL ACCESS TO THORACIC VISCERA

Thoracocentesis (pleural aspiration)

Thoracocentesis or pleural aspiration is an essential step in the assessment of pleural effusions. A chest radiograph will confirm the location and extent of the effusion and clinical examination will identify the best position for aspiration: the posterior midscapular line is a common site. The skin of the desired interspace is cleaned and anaesthetized, and the aspiration needle is inserted at the lower margin of the interspace. The needle is not inserted in the middle of the interspace because the intercostal vessels run along the middle of the interspace posteriorly, and from the axilla forwards onto the anterior chest wall they are protected only by the lower border of the rib. After appropriate local analgesia has been applied, the needle is carefully advanced in a perpendicular direction in the lower portion of the interspace until it enters the pleural space. More complex or small effusions should be aspirated under ultrasound guidance.

Needle thoracocentesis

Needle thoracocentesis is performed in patients in whom a life-threatening tension pneumothorax is suspected. A needle is inserted into the second intercostal space in the midclavicular line on the side of the tension pneumothorax, with the patient in an upright position. A sudden escape of air is heard when the needle enters the parietal pleura. A chest tube must be inserted after this procedure.

Chest drain insertion

The insertion site for a chest drain is usually the fifth intercostal space, just anterior to the midaxillary line on the affected side. A 2 cm horizontal incision is followed by blunt dissection through the subcutaneous tissues to the top of the rib. The parietal pleura is punctured with the tip of a clamp and a gloved finger inserted into the pleural space to free up any adhesions. The chest drain (thoracostomy tube) is then inserted into the pleural space and attached to an underwater sealed container placed below the level of the lungs: the water level rises and falls in the tube with ventilation.

Pericardiocentesis

Pericardiocentesis is performed to aspirate a pericardial effusion or, in an emergency, to decompress a cardiac tamponade, where pressure from blood in the pericardial space prevents the heart chambers from filling during the cardiac cycle, and seriously impairs cardiac output.

Pericardial puncture can be performed in either the fifth or sixth left intercostal space near the sternum (to avoid the internal thoracic artery), or at
the left costoxiphoid angle. The needle is passed 1–2 cm to the left of the costoxiphoid angle at 45° to the skin, and then up and backwards towards the tip of the scapula until it enters the pericardial sac.

Placement of electrocardiograph leads

The 12-lead electrocardiograph (ECG) provides three-dimensional information on the electrical activity of the heart. The limb leads provide information about the electrical activity in the frontal plane. They are placed on the left and right wrists, and the left foot, with the right foot acting as a neutral grounding point. The chest leads provide information about the electrical activity in the horizontal plane. They are placed as follows: V1, right fourth intercostal space, parasternal position; V2, left fourth intercostal space, parasternal position; V3, midpoint of V2 and V4 on the left; V4, fifth intercostal space, midclavicular line on the left; V5, fifth intercostal space, anterior axillary line on the left; V6, fifth intercostal space, midaxillary line on the left.

Thoracotomy incisions

Thoracotomy incisions may be posterolateral, anterolateral or involve a transverse thoracosternotomy.

Posterolateral

A posterolateral incision is most commonly used in thoracic surgery for unilateral pulmonary resections, bullectomy, unilateral lung volume reduction surgery, chest wall resection and oesophageal surgery (Fry 2000). The patient is placed in a lateral decubitus position with adequate support of the elbow, axilla and knee with padding. The standard approach is via an incision from the anterior axillary line which curves about 4 cm below the tip of the scapula and then vertically between the posterior midline and medial edge of the scapula. The incision is usually extended to the level of the spine of scapula. Overall, the incision forms an S-shape in the fifth intercostal space. The sixth or seventh intercostal space is used in oesophageal surgery.

The lower portions of trapezius and latissimus dorsi are divided. Serratus anterior is retracted, and may be divided in a high thoracotomy. The costal muscle and pleura are dissected along the inferior margin of the intercostal space to avoid damaging the neurovascular bundle. A small section of rib is removed at the costovertebral angle to reduce the risk of fracture, particularly in patients older than 40 years. This technique provides good access to the thoracic contents; the main problem is postoperative pain as a consequence of intraoperative musculoskeletal traction.

Anterolateral
Using an anterolateral approach, the patient is placed in the supine position with their arms by their sides. A roll is placed vertically under the back and hips so as to raise the operative side by approximately 45°. The incision is from the midaxillary line over the fifth intercostal space along the inframammary fold, and curves upwards parasternally. The pectoral muscles are divided, and subsequent access to the thorax is similar to that used in the posterolateral approach. However, access is limited, and may be improved by dividing costal cartilages.

'Clam shell'

The transverse thoracosternotomy is known as the 'clam shell' incision. It provides excellent exposure to both sides of the chest and is therefore used in bilateral lung transplantation and in lung volume reduction surgery with bilateral lung resections. The patient is placed in the supine position with a roll vertically along the upper thoracic spine. Bilateral anterolateral incisions are made in the inframammary fold, and the sternum is transected. This allows the upper portion of the thorax to be displaced upwards with a rib-spread, hence the name clam shell. The main disadvantage of the clam shell procedure is the need to transect the sternum: even after careful repair with sternal wires, there is a risk of sternal instability.

Sternotomy

Sternotomy is commonly needed in cardiac surgery. The patient is placed in the supine position with both arms extended by the side. A vertical incision is made in the midline from the suprasternal notch to a point just below the xiphoid process. The tissues around the manubrium and the xiphoid process are mobilized. The pectoral fascia in the midline is incised and the sternum is split and its two edges retracted. The sternum is closed using interosseous wire sutures.

Axillary thoracotomy

The patient is placed in the lateral decubitus position, with arms abducted at 90° and supported on an arm rest. The incision is based along the desired intercostal space, which, for upper thoracic lesions, is the second or third space. Latissimus dorsi is elevated and retracted, whereas serratus anterior is divided in the direction of its fibres. The anterior aspect of serratus anterior is divided to expose the intercostal muscles, which are divided in turn. The overall size of the incision is limited and it provides good access to the upper thorax. Postoperative pain is less than with some other approaches, but the long thoracic nerve (nerve of Bell) may be damaged if serratus anterior is divided too posteriorly.

Thoracoscopic access
Occasionally, video-assisted thoracoscopic surgery is required to assess the mediastinum. The thoracoscope is usually introduced via the fifth intercostal space in the midclavicular line, with additional ports at the third and sixth intercostal spaces to assess the anterior mediastinum. To assess the posterior mediastinum, the thoracoscope is inserted into the seventh intercostal space in the midclavicular line.

*Includes some chest wall and ribcage abnormalities.*

CHAPTER 55 – Mediastinum

Strictly speaking, the mediastinum is the partition between the lungs and includes the mediastinal pleura. However, the term is commonly applied to the region between the two pleural sacs bounded anteriorly by the sternum and posteriorly by the thoracic vertebral column and extending vertically from the thoracic inlet to the diaphragm. For descriptive purposes, this region is arbitrarily divided into superior and inferior mediastina, and the latter is subdivided into anterior, middle and posterior parts. The plane of division into superior and inferior mediastina crosses the manubriosternal joint and the lower surface of the fourth thoracic vertebra (Fig. 55.1). Detailed accounts of some mediastinal contents are also included with descriptions of the respiratory organs (see Ch. 57) and the heart (see Ch. 56).
SUBDIVISIONS OF THE MEDIASTINUM

SUPERIOR MEDIASTINUM

The superior mediastinum lies between the manubrium sterni and the upper four thoracic vertebrae (see Fig. 55.19A–C). It is bounded below by the sternal plane, above by the plane of the thoracic inlet, and laterally by the mediastinal pleurae. It contains the lower ends of sternohyoid, sternothyroid and longus colli; thymic remnants; the internal thoracic arteries and veins, the brachiocephalic veins and the upper half of the superior vena cava, the aortic arch, the brachiocephalic, left common carotid and subclavian arteries and the left superior intercostal vein; the right and left vagi and phrenic nerves, the left recurrent laryngeal nerve, the
cardiac nerves and the superficial part of the cardiac plexus; the trachea, oesophagus and thoracic duct. It also contains the paratracheal, brachiocephalic and tracheobronchial lymph nodes associated with their named structures.

INFERIOR MEDIASTINUM

Anterior mediastinum

The anterior mediastinum lies between the sternal body and pericardium (see Fig. 55.19D,E). It narrows above the fourth costal cartilages, where the pleural sacs come close to each other, and contains loose connective tissue, the sternopericardial ligaments, a few lymph nodes and the mediastinal branches of the internal thoracic artery. The anterior mediastinum may sometimes contain part of the thymus gland or its degenerated remains.

Middle mediastinum

The middle mediastinum is the broadest part of the inferior mediastinum (see Fig. 55.19D,E). It contains the pericardium, the heart and the ascending aorta; the lower half of the superior vena cava receiving the azygos venous arch posteriorly; the tracheal bifurcation and both main bronchi; the pulmonary trunk and right and left pulmonary arteries and veins; the right and left phrenic nerves; the deep part of the cardiac plexus; the tracheobronchial lymph nodes.

Posterior mediastinum

The posterior mediastinum is bounded anteriorly by the bifurcation of the trachea, pulmonary vessels, pericardium and the posterior part of the upper surface of the diaphragm (see Fig. 55.19D,E). Posteriorly, it is bounded by the vertebral column, from the lower border of the fourth to the twelfth thoracic vertebrae, and on each side by the mediastinal pleura. It contains the descending thoracic aorta and the azygos, hemiazygos and accessory azygos veins; the right and left sympathetic chains, the splanchnic nerves and the right and left vagi; the oesophagus; the thoracic duct and posterior mediastinal lymph nodes.
Anatomical pathways exist between the oral cavity and the thorax via the parapharyngeal space and other fascial planes of the neck. The parapharyngeal space is more likely to be infected than any of the other potential tissue spaces in the head and neck: infection can pass from this space to the retropharyngeal and pretracheal spaces and so reach the superior mediastinum, from where it can track down into the anterior part of the inferior mediastinum (see Ch. 28).
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The mediastinum contains the great vessels (i.e. the aortic arch and its branches, the descending thoracic aorta, the pulmonary trunk and the superior vena cava), the pulmonary, internal thoracic and posterior intercostal arteries and veins, and the azygos venous system.

Great vessels of the superior mediastinum

The aortic arch, descending thoracic aorta, pulmonary trunk and superior vena cava are described in Chapter 56.

Azygos venous system

Azygos vein

The azygos vein (Gr. azygos = ‘unpaired’) typically starts from the posterior aspect of the inferior vena cava, at or below the level of the renal veins, although the origin is not constant (Figs 55.2, 55.3; see Fig. 55.14B). When present, the lumbar azygos ascends anterior to the upper lumbar vertebrae. It may pass behind the right crus of the diaphragm or pierce it, or it may traverse the aortic hiatus to the right of the cisterna chyli. Anterior to the twelfth thoracic vertebral body, the azygos is joined by a large vessel formed by the right ascending lumbar and subcostal veins that passes forward and to the right of the twelfth thoracic vertebra behind the right crus: in the absence of a lumbar azygos, this common trunk may form the azygos vein itself. Whatever its origin, the azygos vein ascends in the posterior mediastinum to the level of the fourth thoracic vertebra, where it arches forward above the right pulmonary hilum. It ends in the superior vena cava, before the latter pierces the pericardium. The azygos lies anterior to the bodies of the lower eight thoracic vertebrae, anterior longitudinal ligament and right posterior intercostal arteries. The right greater splanchnic nerve, lung and pleura are right lateral relations. The thoracic duct and aorta and, where the vein arches forward, the oesophagus, trachea and right vagus, are left lateral relations. In the lower thorax the azygos is covered anteriorly by a recess of the right pleural sac and by the oesophagus; it emerges from behind the oesophagus to ascend behind the right hilum. The azygos vein lies close to the right posterolateral aspect of the descending thoracic aorta: aortic pulsations may assist venous return in the azygos and hemiazygos veins.
Fig. 55.2 The superior and inferior extremities of the azygos system of veins and their principal associated veins. The intervening parts have been omitted because diagrams are often topographically misleading. There is considerable variation in the transthoracic parts of the azygos and hemiazygos veins in terms of numbers of radicles, levels of transmedian crossing, etc.
Fig. 55.3 A frequent (perhaps the most common) course followed by the intrathoracic azygos, hemiazygos and accessory azygos veins. Outlines of the root of the right lung and ascending thoracic aorta are included.
Hemiazygos vein

The hemiazygos vein is formed on the left side from the lower three posterior intercostal veins, a common trunk formed by the left ascending lumbar and subcostal veins, and by oesophageal and mediastinal tributaries (Fig. 55.2). It ascends anterior to the level of the vertebral column to the eighth thoracic level then crosses the vertebral column posterior to the aorta, oesophagus and thoracic duct, and ends in the azygos vein (Fig. 55.3). Its lower end is often

Fig. 55.14 Oesophagus. A, Arterial blood supply. B, Venous drainage. (From Sobotta 2006.)
connected to the left renal vein.

**Accessory hemiazygos vein**

The accessory hemiazygos vein descends to the left of the vertebral column, and receives veins from the fourth or fifth to eighth left intercostal spaces; it crosses the seventh thoracic vertebra to join the azygos vein (see Figs 55.5 and 55.6). The accessory hemiazygos vein sometimes receives the left bronchial veins, and it may join the hemiazygos vein, in which case their common trunk opens into the azygos vein.

![Fig. 55.5 The thoracic and right lymphatic ducts. The accessory hemiazygos vein is crossing the median plane lower and the hemiazygos higher than usual. Note also the comments concerning the more common course of the](image-url)
Variations of the azygos veins

The azygos veins vary greatly in their mode of origin, course, tributaries, anastomoses and termination. The accessory hemiazygos is the most variable, and may drain into the left brachiocephalic, azygos or hemiazygos vein. The arrangement shown in Fig. 55.3 represents a common pattern. Commonly, there is a main 'right-sided' azygos and at least some representative of the hemiazygos veins. The latter vary, and one or other may be absent or poorly developed. Very occasionally, independent left and right azygos veins (the early embryonic form) persist, or a single azygos vein may occur in a midline position without hemiazygos tributaries. Retro-aortic transvertebral connections from hemiazygos and accessory hemiazygos veins to the azygos are also extremely variable: there may be up to five connections. When either of the hemiazygos veins is absent, the relevant intercostal veins cross the vertebral bodies and end in the azygos. These transvertebral routes are often very short, because the azygos vein is more commonly anterior to the vertebral column and often passes to the left of the midline for part of its course. When there is congenital interruption of the inferior vena cava (IVC), the azygos vein can become as large as the IVC that it has replaced. Rarely, the azygos arch in the right tracheobronchial angle can be placed more superolaterally in a diagonal accessory azygos fissure in the right upper lobe of the lung as a consequence of failure of embryonic descent.

Internal thoracic arteries and veins

The internal thoracic vessels are described in Chapter 54.

Pulmonary arteries and veins

The pulmonary vessels are described in Chapter 57.

Posterior intercostal arteries and veins

The posterior intercostal veins accompany their arteries in 11 pairs; they are described in Chapter 54.
MEDIASTINAL LYMPH NODES

The mediastinal lymph nodes (Fig. 55.4; see Fig. 56.3) are classified into regional lymph node stations by thoracic surgeons for the purposes of staging lung cancer. The stations are defined as follows: **Station 1**: highest mediastinal nodes lie above a horizontal line of the level at which the left brachiocephalic vein crosses the trachea. **Station 2**: upper paratracheal nodes lie below the line of the highest mediastinal nodes and above a line drawn horizontally at the level of the upper border of the aortic arch. **Station 3**: prevascular and retrotracheal nodes lie behind the trachea but in front of the great vessels. **Station 4**: lower paratracheal nodes lie below the upper margin of the aortic arch and down to the upper margin of the corresponding upper lobe bronchus. On the right side, this is the upper margin of the right upper lobe bronchus; the majority of nodes in this area tend to be positioned anterolateral to the trachea. On the left side, the nodes are located below the upper margin of the aortic arch and above the margin of the left upper lobe bronchus. They lie medial to the ligamentum arteriosum and are usually lateral to the trachea. **Station 5**: subaortic nodes lie in the aortopulmonary window and are situated lateral to the ligamentum arteriosum or aorta or left pulmonary artery, but proximal to the first division of the left pulmonary artery. **Station 6**: para-aortic nodes lie between the upper margin of the aortic arch and lateral to the ascending aorta and aortic arch. **Station 7**: subcarinal nodes lie below the carina of the trachea, but are not associated with the lower lobe bronchi. **Station 8**: para-oesophageal nodes lie at either side of the oesophagus, well below the level of the subcarinal nodes. **Station 9**: pulmonary ligament nodes lie within the pulmonary ligament.
Involvement of these lymph nodes by cancer cells has important prognostic implications and influences the choice of treatment (Mountain & Dresler 1997). The staging system for lung cancer classifies involvement of ipsilateral hilar lymph nodes as N1, ipsilateral mediastinal lymph nodes as N2, contralateral mediastinal/hilar nodes as N3 and supraclavicular/scalene nodes as M1 (distant metastases).
These groups are not sharply demarcated. Pulmonary nodes become continuous with the bronchopulmonary nodes, and these in turn merge with the inferior and superior tracheobronchial nodes, which are continuous with the paratracheal group. Afferents of tracheobronchial nodes drain the lungs and bronchi, the thoracic part of the trachea, the heart and some efferents of the posterior mediastinal nodes. Their efferent vessels ascend on the trachea to unite with efferents of the parasternal and brachiocephalic nodes as the right and left bronchomediastinal trunks. The right trunk may occasionally join a right lymphatic duct or another right-sided lymph trunk and the left trunk may join the thoracic duct, but usually they open independently in or near the ipsilateral jugulosubclavian junction (see Ch. 28).

**Mediastinoscopy**

In cervical mediastinoscopy, a transverse incision is made in the suprasternal notch through the deep lamina of the deep cervical fascia after retraction of sternohyoid and sternothyroid which lie within its superficial lamina. The pretracheal plane is dissected along the anterior surface of the trachea and a space is created between the trachea and the brachiocephalic artery anteriorly down to the level of the carina and along both sides of the trachea and main bronchi. This allows insertion of the endoscope to inspect and biopsy lymph node masses in the upper paratracheal (station 2), lower paratracheal (station 4) and subcarinal nodes (station 7). The anterior part of the superior mediastinum is more difficult to assess by mediastinoscopy and usually requires an anterior mediastinotomy, where the mediastinoscope is inserted retrosternally along the prevascular plane. The nodes at stations 5 and 6 of the mediastinum can be accessed by this technique.
THORACIC DUCT

In adults, the thoracic duct, including the confluence of lymph trunks (or the cisterna chyli in the small proportion of individuals in whom the latter is saccular), is 38–45 cm in length and extends from the second lumbar vertebra to the base of the neck (Fig. 55.5). Starting from the superior pole of the confluence near the lower border of the twelfth thoracic vertebra (see Ch. 62), the thoracic duct traverses the retrocrural space of the diaphragm with the aorta, azygos and hemiazygos veins, then ascends in the posterior mediastinum, on the right of the midline, between the descending thoracic aorta (on its left) and the azygos vein (on its right). The vertebral column, the right aortic intercostal arteries and terminal segments of the hemiazygos and accessory hemiazygos veins are posterior relations. The diaphragm and oesophagus are anterior; a recess of the right pleural cavity may separate the duct and oesophagus. At the level of the body of the fifth thoracic vertebra, the duct gradually inclines to the left, enters the superior mediastinum and then ascends to the thoracic inlet along the left border of the oesophagus. In this part of its course the duct is first crossed anteriorly by the aortic arch and then runs posterior to the initial segment of the left subclavian artery, in close contact with the left mediastinal pleura. Passing into the neck, it arches laterally at the level of the transverse process of the seventh cervical vertebra. Its arch rises 3 or 4 cm above the clavicle and curves anterior to the vertebral artery and vein, the left sympathetic trunk, the thyrocervical trunk or its branches, the left phrenic nerve and the medial border of scalenus anterior. It passes posterior to the left common carotid artery, vagus nerve and internal jugular vein. Finally, the duct descends anterior to the arched cervical first part of the left subclavian artery and ends by opening into the junction of the left subclavian and internal jugular veins (see Fig. 28.16A). It may also open into either of the great veins, near the junction, or it may divide into a number of smaller vessels before terminating. In rare individuals there is no apparent thoracic duct on the left. Several terminal openings sometimes occur. Patterns vary greatly in different studies, but the commonly reported sites of termination are the internal jugular vein, jugulosubclavian junction and subclavian vein. Termination in the left brachiocephalic vein occurs occasionally.

At its abdominal origin, the thoracic duct is usually 5 mm in diameter, diminishing in calibre at midthoracic level, and then in approximately half of individuals is again slightly dilated before its termination. It is slightly sinuous, constricted at intervals and appears varicose. It may divide in its mid course into two unequal vessels that soon reunite, or into several small branches that form a plexus before continuing as a single duct. At a higher level it occasionally bifurcates, the left branch ending as usual, the right branch diverging to join one of the right lymph trunks or, when present, a right lymphatic duct. The combined vessel usually opens into the right subclavian
vein. The thoracic duct has several valves corresponding to sites exposed to pressure. At its termination a bicuspid valve faces into the vein to prevent or reduce reflux of blood: post mortem, blood regurgitates freely into the duct.

Anomalies of the thoracic duct may be delineated by dissection into the inguinal lymphatics followed by cannulation and subsequent injection of an oily contrast medium (lipiodol) followed by plain films or CT.

**TRIBUTARIES**

Bilateral descending thoracic lymph trunks from intercostal lymph nodes of the lower six or seven intercostal spaces of both sides traverse the retrocrural space and join the lateral aspects of the thoracic duct in the abdomen immediately after its origin. Bilateral ascending lumbar lymph trunks from the upper lateral aortic nodes ascend and pierce their corresponding diaphragmatic crus, and then join the thoracic duct at a variable level within the thorax. The upper intercostal trunks drain the intercostal nodes in the upper five or six left intercostal spaces. The mediastinal trunks drain various nodal groups and provide paths to the thoracic duct from the convex diaphragmatic aspect of the liver, the diaphragm, the pericardium, heart and oesophagus. The left subclavian trunk usually joins the thoracic duct, but may open independently into the left subclavian vein. The left jugular trunk usually joins the thoracic duct, but may open independently into the left internal jugular vein. The left bronchomediastinal trunk occasionally joins the thoracic duct, but usually has an independent venous opening.

Many of the trunks listed above are described as possessing terminal bicuspid valves, which possibly prevent reflux of lymph.
INJURY DURING OESOPHAGEAL SURGERY

The thoracic duct is vulnerable to damage after thoracic, particularly oesophageal, surgery (Wemyss-Holden et al 2001). The incidence is between 0.2% and 3% and increases with transhiatal and thoracoscopic procedures. Thoracic duct laceration is a potentially life-threatening complication: mortality rates are more than 50% with conservative management and as high as 10–16% even after early surgical duct ligation. Rupture of the thoracic duct leads to leakage of chyle, which is rich in lipid, protein and lymphocytes, and hence a progressive nutritional and immune deficit occurs. Fortunately, the incidence of true thoracic duct transection is rare, and cases in which there are some postoperative chylous effusions are usually the result of damage to some of the tributaries of the thoracic duct, rather than to the duct itself. These are usually self-limiting and respond to conservative treatment.

The variable course of the thoracic duct, coupled with failure to identify it at surgery, may lead to its inadvertent incision or transection. The greater incidence of injury with transhiatal resection may be attributable to shear forces during the mobilization of the distal oesophagus, whereas the limited field of view probably contributes to the greater incidence of thoracic duct injury during thoracoscopic surgery. Injury should be suspected in the postoperative period if there is an enlarging mediastinal silhouette on serial chest radiographs, or if there is significant drainage of a cream-coloured liquid from the chest or abdominal drains. In cases of uncertainty, an electrophoretic confirmation for the presence of chylomicrons in the pleural fluid is diagnostic.
DEVELOPMENT

The development of the thoracic duct is described in Chapter 59.
RIGHT LYMPHATIC TRUNK

The right lymphatic trunk (Fig. 55.5) has a variable anatomy, which includes doubling of the duct, left-sided, right or bilateral termination. The plexiform nature of the trunks from which the thoracic duct develops leads to a number of possible abnormalities. The most common is duplication of the duct for a variable part of its course and subsequent merging to form a single duct which drains into the left internal jugular trunk. Occasionally the duct has dual terminations in the right and left internal jugular veins, and rarely it terminates only into the right internal jugular vein.
AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system in the thorax consists of right and left ganglionated sympathetic chains and vagi and the cardiac, pulmonary and oesophageal plexuses. The cardiac plexus is described in Chapter 56, the pulmonary plexus is described in Chapter 57, and the oesophageal plexus is described below.

THORACIC SYMPATHETIC TRUNK

The thoracic sympathetic trunk (Fig. 55.7; see Fig. 15.13) contains ganglia almost equal in number to those of the thoracic spinal nerves (usually 11, occasionally 12, rarely 10 or 13). Almost always, the first thoracic ganglion is fused with the inferior cervical ganglion, forming the cervicothoracic ganglion. Occasionally, the second thoracic ganglion may be included in this fusion, in which case the succeeding ganglion is counted as the second in order to make the other ganglia correspond numerically with other segmental structures. Except for the second and lowest two or three, the thoracic ganglia lie against the costal heads, posterior to the costal pleura. The second thoracic sympathetic ganglion is commonly located in the second intercostal space, and the lowest two or three ganglia lie lateral to the bodies of the corresponding vertebrae. Caudally, the thoracic sympathetic trunk passes dorsal to the medial arcuate ligament (or through the crus of the diaphragm) to become the lumbar sympathetic trunk.
The ganglia are small and interconnected by intervening segments of the trunk. The classic description is that two or more rami communicantes, named white and grey, connect each ganglion with its corresponding spinal nerve, the white rami joining the nerve distal to the grey. Variation in this pattern is not uncommon, especially in the upper thoracic levels: these variations are rarely bilaterally symmetrical. Additional ascending and descending rami to higher and lower levels respectively issue from the second sympathetic ganglion (54% and 46% respectively), from the third ganglion (6% and 25%), and from the fourth ganglion (5% and 8%) (Cho et al 2005). The ascending ramus from the second ganglion is sometimes called the nerve of Kuntz. The anatomical variations displayed by the communicating rami and in the location of the second sympathetic ganglion might explain some surgical failures and symptom recurrences). Occasionally, a grey
and a white ramus fuse to form a 'mixed' ramus.

The medial branches from the upper five ganglia are very small, and supply filaments to the thoracic aorta and its branches; they form a fine thoracic aortic plexus on the aorta with filaments from the greater splanchnic nerve. Rami of the second to fifth or sixth ganglia enter the posterior pulmonary plexus. Others, from the second to fifth ganglia, pass to the deep (dorsal) part of the cardiac plexus. Small branches of these pulmonary and cardiac nerves pass to the oesophagus and trachea. The medial branches from the lower seven ganglia are large; they supply the aorta and unite to form the greater, lesser and lowest splanchnic nerves (the last two are not always identifiable).

The greater splanchnic nerve consists mainly of myelinated preganglionic efferent and visceral afferent fibres, and is formed by branches from the fifth to ninth or tenth thoracic ganglia; fibres in the upper branches may be traced to the first or second thoracic ganglia. Its roots vary from one to eight, four being the most usual number. It descends obliquely on the vertebral bodies, supplies branches to the descending thoracic aorta and perforates the ipsilateral crus of the diaphragm to end mainly in the coeliac ganglion, but partly in the aorticorenal ganglion and suprarenal (adrenal) gland. A splanchnic ganglion exists on the nerve opposite the eleventh or twelfth thoracic vertebra in a majority of individuals.

The lesser splanchnic nerve, formed by rami of the ninth and tenth (sometimes the tenth and eleventh) thoracic ganglia and the trunk between them, pierces the diaphragm with the greater splanchnic nerve and joins the aorticorenal ganglion.

The lowest (least) splanchnic nerve (or renal nerve) from the lowest thoracic ganglion enters the abdomen with the sympathetic trunk to end in the renal plexus.

The greater splanchnic nerve is always present, the lesser is usually present, and the least is often present. A fourth (accessory) splanchnic nerve has been described.

**Thoracic sympathectomy**

Endoscopic thoracic sympathectomy (ETS) is the method of choice to cure moderate and severe hyperhidrosis of the palms, phobic facial blushing, endstage severe Raynaud's disease with peripheral ulcers, and severe reflex sympathetic dystrophy. The treatment of the last two disorders by ETS is controversial because the effect is usually transitory. ETS is very successful in curing patients with hyperhidrosis and phobic facial blushing: pain syndromes have a significantly poorer outcome.

The operation involves making tiny incisions behind the anterior pectoral fold in the axilla, and insufflating a small amount of carbon dioxide into the thoracic cavity to allow access with a modified thoracoscope. In the treatment of phobic facial blushing, it is sufficient to divide the fibres that run superiorly from the second thoracic ganglion over the neck of the second rib, leaving the second
ganglion almost intact. Treatment of palmar hyperhidrosis requires ablation thermocoagulation of the sympathetic trunk over the necks of the third and fourth ribs, taking care to avoid any spreading of thermal energy along the trunk to avoid damaging the more superior stellate ganglion (see 'Horner's syndrome' paragraph below). The risk of compensatory sweating is greatly reduced, though not completely excluded, by limiting the number of ganglia treated to an absolute minimum. As an additional procedure, dividing the inconstant sympathetic pathways (nerve of Kuntz, ascending or descending additional rami communicantes) on the second, third and fourth ribs may improve surgical outcomes.

The effect is immediately evident: the patient awakes from anaesthesia with dry and warm hands. In many cases, even hyperhidrosis of the feet improves, but the underlying anatomical/physiological mechanisms are not yet properly understood (Gofeld & Faclier 2006). Surgical complications are very rare: Horner's syndrome is the most feared, and is caused by damage to the stellate ganglion and interruption of the sympathetic fibres from T1 which ascend around the arteries supplying the head and neck (see Ch. 28).

Side effects include compensatory sweating (ranging from barely noticeable to quite disturbing) in other locations of the body on exercise or from exposure to high temperatures in up to 70% of patients. This is severe in 5% of patients and may be more frequent in those operated on for axillary hyperhidrosis (when two more inferior ganglia have to be divided): some surgeons do not now consider isolated axillary hyperhidrosis as an indication for this procedure. Gustatory or olfactory sweating may also occur in up to a third of patients, but is rarely considered a problem. Other documented side effects are the inability to raise the heart rate when working-out physically, and in some cases this has led to decreased ability to perform work and daily activities. Some patients also experience an uncomfortable sensation of not being able to control their body temperature.
VAGUS NERVE IN THE MEDIASTINUM

The vagus nerve contains preganglionic parasympathetic fibres that arise in its dorsal nucleus and travel in the nerve and in its pulmonary, cardiac, oesophageal, gastric, intestinal and other branches. Some cardiac parasympathetic fibres may originate from neurones in or near the nucleus ambiguus. The proportion of efferent parasympathetic fibres in the vagus varies at different levels, but is small relative to its sensory and sensorimotor content. Efferent fibres relay in minute ganglia in the visceral walls.

Cardiac branches join the cardiac plexuses and relay in ganglia that are distributed freely over both atria in the subepicardial tissue. The terminal fibres are distributed to the atria and the atroventricular bundle; they are concentrated around the sinuatrial and, to a lesser extent, the atroventricular nodes (see Ch. 56). Cardiac branches slow the cardiac cycle and diminish the force of contraction. It has been claimed that the vagus can only influence ventricular muscle via their effect on the atroventricular node, even though postganglionic parasympathetic innervation of the ventricles is sparse. The smaller branches of the coronary arteries are innervated mainly via the vagus, whereas larger arteries, with a dual innervation, are chiefly supplied by sympathetic fibres. Pulmonary branches are motor to the circular smooth muscle fibres of the bronchi and bronchioles and are therefore bronchoconstrictor; synaptic relays occur in the ganglia of the pulmonary plexuses.

The distribution of the vagi to the abdominal viscera is described in relevant chapters in the section on Abdomen and Pelvis.

Right vagus

The right vagus nerve descends posterior to the internal jugular vein and crosses the first part of the subclavian artery to enter the thorax. It descends through the superior mediastinum, at first behind the right brachiocephalic vein, and then to the right of the trachea and posteromedial to the right brachiocephalic vein and superior vena cava. The right pleura and lung are lateral to it above and are separated from it below by the azygos vein, which arches forwards above the right pulmonary hilum (Fig. 55.6). It passes behind the right main bronchus and lies on the posterior aspect of the right hilum, where it divides into the posterior pulmonary (or bronchial) branches. The latter unite with rami from the second to fifth or sixth thoracic sympathetic ganglia to form the right posterior pulmonary plexus. Two or three branches descend from the caudal part of this plexus on the posterior surface of the oesophagus and join a left vagal branch to form the posterior oesophageal plexus. A vagal trunk containing fibres from both right and left vagi leaves the plexus and runs down on the posterior surface of the oesophagus. It enters the abdomen by passing through the diaphragmatic oesophageal opening.

Left vagus

Fig. 55.6 The mediastinum. A, Right lateral aspect. B, Left lateral aspect. (From Sobotta 2006.)
The left vagus enters the thorax between the left common carotid and subclavian arteries and behind the left brachiocephalic vein. It descends through the superior mediastinum and crosses the left side of the aortic arch to pass behind the left pulmonary hilum (Fig. 55.6). Above the aortic arch, it is crossed anterolaterally by the left phrenic nerve, and on the arch by the left superior intercostal vein. Behind the hilum it divides into the posterior pulmonary (or bronchial) branches, which unite with rami of the second to fourth thoracic sympathetic ganglia to form the left posterior pulmonary plexus. Two or three branches descend anteriorly on the oesophagus and join with a ramus from the right posterior pulmonary plexus to form the anterior oesophageal plexus. A trunk containing fibres from both vagi descends anterior to the oesophagus and enters the abdomen through the oesophageal diaphragmatic opening.
**THYMUS**

The thymus (Figs 55.8, 55.9) is one of the two primary lymphoid organs, the other being the bone marrow. It is an encapsulated soft, bilobed organ, the two parts being joined in the midline by connective tissue that merges with the capsule of each lobe. The latter may normally have adhesions to the fibrous pericardium that necessitate limited pericardiectomy during thymectomy. The thymus is visible on CT and MRI axial sections just anterior to the ascending aorta and inferior to the left brachiocephalic vein; the CT attenuation in younger individuals is homogeneous and similar to or greater than that of muscle, and the signal intensity with MRI on T₂-weighted images is similar to or greater than that of fat.

Fig. 55.8 The neonatal thymus.
RELATIONS

The thymus is largest in the early part of life, particularly around puberty, and persists actively into old age despite considerable fibrofatty degeneration which sometimes hides the existence of thymic tissue. The greater part of the thymus lies in the superior mediastinum and anterior part of the inferior mediastinum, and the lower border of the thymus reaches the level of the fourth costal cartilages. Superiorly, extensions into the neck are common, reflecting the (bilateral) embryonic origins of the thymus from the third pharyngeal pouch. Its upper poles join at, and extend above, the level of the suprasternal notch; the left usually extends higher and is seen first behind the strap muscles during the initial stages of transcervical thymectomy (see p. 949). It sometimes reaches the inferior poles of the thyroid gland or even higher, and is connected to the thyroid gland by the thyrothymic ligament. Its shape is largely moulded by adjacent structures. Inferiorly, the lower end of the right lobe commonly lies between the right side of the ascending aorta and the right lung, anterior to the superior cava. Anteriorly lie sternohyoid, sternothyroid and fascia (in the neck), and the manubrium sterni, internal thoracic vessels and upper three costal cartilages (in the thorax). The pleurae lie laterally and the phrenic nerves are anterolateral and inferior. Posteriorly, the thymus is in contact with the vessels of the superior mediastinum (the left brachiocephalic vein may be partly embedded in the gland), the upper part of the thoracic trachea and the anterior surface of the heart. Thoracic surgeons performing thymectomies must be aware of the anatomic variation where the upper poles may lie posterior to the left brachiocephalic vein.

Separated thymic tissue is often found scattered around the gland, and ectopic thymic rests are sometimes discovered in unusual mediastinal locations. Small accessory
nodules may occur in the neck; they represent portions that have become detached during their embryological descent. Thin strands of thymic tissue may occur along the line of descent, and may reach as high as the thyroid cartilage or above. Connective tissue marking the embryological pathway may run between the thymus and the parathyroids.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The thymus is supplied mainly from branches of the internal thoracic and inferior thyroid arteries, which also supply the surrounding mediastinal connective tissue. A branch from the superior thyroid artery is sometimes present. There is no main hilum, but arterial branches pass either directly through the capsule or, more often, into the depths of the interlobar septa before entering the thymus at the junction of the cortex and medulla.

Veins

Thymic veins drain to the left brachiocephalic, internal thoracic and inferior thyroid veins and occasionally directly into the superior vena cava. One or more veins often emerge medially from each lobe of the thymus to form a common trunk opening into the left brachiocephalic vein.

Lymphatic drainage

The thymus has no afferent lymphatics. Efferent lymphatics arise from the medulla and corticomedullary junction and drain through the extravascular spaces in company with the arteries and veins that supply the thymus. Thymic lymphatic vessels end in the brachiocephalic, tracheobronchial and parasternal nodes.
INNERVATION

The thymus is innervated from the sympathetic chain via the cervicothoracic (stellate) ganglion or ansa subclavia and from the vagus. Branches from the phrenic and descending cervical nerves are distributed mainly to the capsule. The two lobes are innervated separately through their dorsal, lateral and medial aspects. During development and before its descent into the thorax, the thymus is innervated by the vagus in the neck. After its descent, the thymus receives a sympathetic innervation via fibres that travel along the vessels: postganglionic sympathetic terminations branch radially and form a plexus with the vagal fibres at the corticomedullary junction.

Innervation is complete by the onset of thymic function. Many of the autonomic nerves are doubtless vasomotor, but other terminal branches (at least in rodents) ramify among the cells of the thymus, particularly the medulla, suggesting that they may have other roles. The medulla contains a number of different types of non-lymphoid cells, including cells positive for vasoactive intestinal polypeptide and acetylcholinesterase, large non-myoid cells, and cells containing oxytocin, vasopressin and neurophysin, of possible neural crest origin. The roles of the nervous system and other neuroendocrine elements in the overall biology of the thymus are little understood.
MICROSTRUCTURE

The thymus is responsible for the provision of thymus-processed (T) lymphocytes to the entire body, and provides a unique microenvironment in which T-cell precursors (thymocytes) undergo development, differentiation and clonal expansion to deliver the exquisitely specific T-cell response, simultaneously acquiring immune tolerance to the body’s own components. These steps involve intimate interactions between thymocytes and other cells (mainly epithelial cells and antigen-presenting cells) and chemical factors in the thymic environment. The thymus is also part of the neuroimmunological and neuroendocrine axes of the body, and it both influences and is influenced by the products of these axes. Its activity therefore varies throughout life under the influence of different physiological states, disease conditions and chemical insults, such as hormones, drugs and pollutants.

General architecture

It is useful to consider the embryological origins of the thymus in order to understand its cellular organization. The thymus is derived from a number of sources, including epithelial derivatives of the pharyngeal pouches, mesenchyme, haemolymphoid cells and vascular tissue. In section, the thymus can be seen to consist of an outer cortex of densely packed cells mainly of the T-lymphocyte lineage (thymocytes) and an inner medulla with fewer lymphoid cells (Fig. 55.10).
Both thymic lobes have a loose fibrous connective tissue capsule, from which septa penetrate to the junction of the cortex and medulla, and partially separate the irregular lobules (see Fig. 55.12), which are each 0.5–2.0 mm in diameter. The connective tissue septa form a route of entry and exit for blood vessels and nerves and carry efferent lymphatics. Most migrant cells enter or leave the thymus by this route.
In each lobule, the cortex is composed of a superficial subcapsular cortex (a narrow band of cells immediately beneath the capsule), and the main cortex, which is much more extensive. The central medulla of both thymic lobes is continuous from one lobule to the next.

**Epithelial framework**

Unlike other lymphoid structures, in which the supportive framework is chiefly collagenous reticular tissue, the thymus contains a network of interconnected epithelial cells (Fig. 55.10) which create an appropriate microenvironment, by cell–cell contact and the release of paracrine factors, in which thymic lymphocytes (T cells) develop and mature. Although differing in morphology, all the epithelial cells of the thymus share a common origin from pharyngeal endoderm. They vary in size and shape according to their positions within the thymus. Typically they have pale, oval nuclei, a rather eosinophilic cytoplasm and intercellular desmosomal attachments. Intermediate filament bundles of cytokeratin lie within their cytoplasm. The subcapsular cells form a continuous external lining to the thymus beneath its fibrous capsule, and follow its lobulated profile, ensheathing the vessels that pass into it, and contributing to the functional blood–thymus barrier. Other cortical epithelial cells form a loose mesh of long cytoplasmic processes, whereas medullary epithelial cells tend to form more solid cords as well as thymic or Hassall's corpuscles: lymphocytes lie within the interstices of the mesh or between the cords. Large epithelial cells may be associated with around 50 or more thymocytes and are sometimes called thymic nurse cells.

Hassall's corpuscles are whorls of flattened, concentrically layered medullary epithelial cells, from 30 to 100 µm in diameter, and are characteristic features of the thymic medulla (Figs 55.10, 55.11). They start to form before birth and their numbers increase throughout life. Their function is not clear, although they may represent a site for removal of dying, apoptotic thymocytes, because their centres are eosinophilic, partly keratinized and often contain cellular debris. Corpuscles with a similar appearance have been described in the palatine tonsil.
Other non-lymphocytic thymic cells

The thymus also contains cells of the myeloid lineage, fibroblasts and myoid cells. Myeloid lineage cells include monocytes at the corticomedullary junction; mature macrophages throughout, but particularly in the cortex; and interdigitating dendritic (antigen-presenting) cells at the corticomedullary junction and in the medulla. Some dendritic cells are of lymphoid rather than myeloid origin. Fibroblasts are found in the capsule, perivascular spaces and medulla, but are infrequent in the cortex, except in the involuted thymus. Myoid cells, which are relatively rare, are situated mainly in the medulla and at the corticomedullary junction. They are large, rounded cells, and possess a central nucleus surrounded by irregularly arranged bundles of myofilaments. Their functions are unknown, although it has been suggested that their contractions might aid the movement of lymphoid cells across or out of the thymus.

Thymocytes

The cortex is densely packed with small thymocytes (thymic lymphocytes, presumptive T cells). They occupy the interstices of the epithelial reticulum, which in histological sections they largely obscure, and form 90% of the total weight of the neonatal thymus. A distinct subcapsular zone houses the thymic stem cells and lymphoblasts undergoing mitotic division. The first stem cells to enter the thymus in the embryo come from the yolk sac and liver during their haemopoietic phases. During later developmental periods, it is probable that all thymic lymphocytes originate in the bone marrow before passing in the blood stream to the thymus.

Thymocytes undergo mitosis in all cortical zones as the differentiating T cells mature, gradually moving deeper into the cortex (Fig. 55.12). The processes of thymocyte
development and maturation to generate T cells depend on the microenvironment provided by epithelial cells, dendritic cells, macrophages and fibroblasts. T cells which either fail to recognize self-MHC (histocompatibility) molecules or which recognize self-antigens die by apoptosis, in order to achieve functional immune reactivity and maintain self-tolerance, respectively. Over 95% of cortical thymocytes die within the thymus; the surviving T cells migrate through the walls of venules and efferent lymphatics to enter the circulation and populate secondary lymphoid tissues.

**Microcirculation**

**Cortex**

The pattern of blood flow differs in the cortex and medulla. Major blood vessels enter the gland at the corticomedullary junction and pass within each lobe, giving off small capillaries to the cortex and larger vessels to the medulla. Most cortical capillaries loop around at different depths in the cortex and join venules at the corticomedullary junction; some continue through the cortex and join larger venules running in the capsule which leave the thymus. These smaller cortical capillaries usually have a narrow perivascular space, which sometimes contains pericytes and other cells, but rarely nerves. Sheaths of thymic epithelial cells of the blood–thymus barrier lie between the perivascular space and cortical thymocytes.

**Medulla**

Medullary blood vessels are not as well protected by epithelial cells, and those of the corticomedullary junction are only partially ensheathed, usually on their cortical aspect. Medullary vessels are very variable in size, and some may have short lengths of cuboidal endothelium similar to those in lymph nodes and mucosa-associated lymphoid tissue.
DEVELOPMENT

The embryology and prenatal development of the thymus are described in Chapter 35.

**Thymic changes during postnatal life**

At birth the thymus is most often bilobar. It is 4–6 cm long, 2.5–5 cm wide and 1 cm thick. The thickest part of the gland at birth is not at the thoracic inlet, but immediately above the base of the heart. During childhood the thymus narrows and lengthens and the cervical portion becomes less noticeable. CT and imaging studies of the thorax reveal that the right lobe of the thymus typically measures 9 mm in thickness, and the left 11 mm, in normal children. After the age of 20 years, it decreases to 5–6 mm in thickness (Fig. 55.12).

The thymus is largest relative to the body at birth, with a mass of 10–15 g. It rapidly increases to 20 g, and subsequently remains at that mass. Studies of thymic mass after sudden death have recorded a wide variation at all ages, but the general pattern is that, after the first year of life, when there is an increase, the mean mass is fairly constant at 20 g until the sixth decade, when a reduction occurs. However, although the mass of the thymus may be fairly constant, it becomes increasingly infiltrated by adipose tissue and so the total amount of active lymphoid tissue becomes progressively smaller with time. At birth, individual adipocytes may be seen in connective tissue septa, and increased numbers are found within the cortex in the second and third decades. Fatty infiltration is usually complete by the fourth decade, when only the medulla and small patches of associated cortex are spared. This process is independent of the level of obesity of the individual.

In children the gland is more pyramidal in shape and firmer than in later life, when the amount of lymphoid tissue is greatly reduced. In the fresh state it is deep red, reflecting its rich blood supply (Fig. 55.9). With age it becomes thinner and greyer, and infiltrated by yellow adipose tissue. Each of the two lobes is partially divided by the ingrowth of shallow septa, so that, superficially, the gland appears lobulated. As fatty atrophy proceeds, this lobulation becomes more distinct. The older thymus can be distinguished from the surrounding mediastinal fat only by the presence of its capsule. However, even within greatly atrophied glands there are usually greyer areas around blood vessels formed by persistent lymphoid tissue. Thymocyte production and differentiation persist throughout life: T cells from the thymus continue to populate the peripheral lymphoid tissue, blood and lymph.

**Thymoma and myasthenia gravis**

Thymic tumours may compress the trachea, oesophagus and large veins in
the neck, causing hoarseness, cough, dysphagia and venous engorgement of the head and neck. Thymomas tend to have an inhomogeneous signal intensity on MRI. They may develop in one lobe of the thymus without affecting the other. Many affected patients also have myasthenia gravis and other autoimmune conditions. Myasthenia gravis, a chronic autoimmune disease of adults, presents as a diminution in power of repetitive contraction in certain voluntary muscles. Although there may be more than one condition with these signs, myasthenia gravis is essentially an autoimmune disease in which acetylcholine receptor proteins of neuromuscular junctions are attacked by autoantibodies. Muscles commonly involved are levator palpebrae superioris (leading to ptosis) and the extraocular muscles (leading to diplopia). Other muscles in the face, jaws, neck and limbs may be involved, and in severe cases the ventilatory muscles are compromised. About 10% of Caucasian individuals with myasthenia gravis have a thymoma and 50% have medullary follicular hyperplasia, the latter predominantly females younger than 40 years of age with strong expression of HLA-B8-DR3 in whom thymectomy often results in symptomatic improvement. In the absence of a thymoma, the onset of myasthenia gravis occurs after 40 years of age in patients with an HLA-B7-DR2 phenotype, except for a group in whom weaknesses are restricted to eye and eyelid movements.

**Thymectomy**

In myasthenia gravis, patient selection for thymectomy begins with a referral from a neurologist. The strongest association between thymectomy and an improved clinical course has been seen in female myasthenics with systemic weakness; controversial groups include the elderly and those with only ocular symptoms. A new transcervical approach for thymectomy is being performed more commonly, but the traditional sternal splitting approach is still the commonest technique. After a lower transverse neck incision, the ligamentous insertions of the sternocleidomastoids are divided vertically with electrocautery to allow improved exposure into the substernal plane. The upper edge of the skin flap is elevated in the subplatysmal plane to the level of the inferior border of the thyroid gland. The strap muscles are separated longitudinally along their midline raphae and the upper poles of the thymus gland are detected behind. Typically, the larger left superior pole is identified first and dissected free down towards the point at which it merges with the right superior pole just above the jugular notch. The prethymic plane is created by blunt finger dissection anterior then below the left brachiocephalic vein into the substernal location. The thymus is then gently retracted forward and upward to display the veins draining the thymus directly into the left brachiocephalic vein, which are divided. The dissection is then carried along the posterior aspect of the thymus into the mediastinum. The thymus generally remains completely encapsulated and is separated without difficulty from the pericardium (occasionally adhesions necessitate a limited pericardiectomy). Further inferiorly, depression of the great vessels allows
direct visualization into the aortopulmonary window for complete removal of
the thymus in this vicinity. Some directly contributing blood vessels may be
encountered in the form of veins draining into the superior vena cava on the
right, or small branches from either of the internal thoracic arteries. These
can be dealt with using electrocautery, although care should be taken to
avoid injury to the phrenic nerves (for this reason, patients are generally not
given a paralytic agent during the course of the anaesthetic, so that the
phrenic nerve may be identified intraoperatively).

In most cases the thymus gland is removed completely with both upper and
lower poles intact. Careful inspection of the remaining tissue in the
mediastinum is performed to identify any possible anatomic anomalies that
might result in retained thymic tissue after the operation. The most common
anomaly is the unanticipated location of the upper poles of the thymus behind
the brachiocephalic vein. The aortopulmonary window is also a common
location for thymic tissue and this area is sometimes difficult to expose with a
transcervical approach. Any suspicious foci of fat in the mediastinum are
removed, and, if necessary, sent for frozen section to ascertain whether or
not they contain thymic tissue.

The thymus is essential to the normal development of lymphoid tissues
during neonatal and early postnatal life. Thymectomy during this period leads
to a progressively fatal condition, with hypoplasia of the peripheral lymphoid
organs, wasting and an inability to mount an effective immune response. By
puberty, when the main lymphoid tissues are fully developed, thymectomy is
less debilitating, but a reduction in effective responses to novel antigens
ultimately ensues.

**Congenital anomalies of the thymus**

Undescended thymus, accessory thymic bodies and rare cysts of the third
branchial pouch are of no clinical significance (except where thymectomy is
indicated). Patients with thymic agenesis, aplasia and hypoplasia, as in
severe combined immune deficiency disease, have reduced lymphocyte
numbers, and early death from infection is common. Most cases are familial,
with autosomal recessive genes. In young children, a large normal thymus
may press on the trachea, causing attacks of ventilatory stridor.

**Mediastinal parathyroid adenoma**

When primary hyperparathyroidism is diagnosed, surgical excision of the
causative parathyroid adenoma (occasionally multiple) is usually performed
whether or not symptoms are present. Approximately 3% of parathyroid
tumours are found in glands in the mediastinum; 80% of these ectopic
adenomas are found in the superior or anterior part of the inferior
mediastinum, derived from inferior glands that descend with the thymus in
the embryo, and the remainder are found in the posterior mediastinum. Preoperative localization may help decrease surgical exploration time and morbidity: the sensitivity of technetium-99m sestamibi imaging for identification of parathyroid adenomas exceeds 90%. MRI has a sensitivity of up to 75%, while CT and suprasternal sonography are less sensitive (Iyer et al 1999). Venous sampling may also be used in cases of diagnostic difficulty.

**Congenital mediastinal cysts**

These form up to 30% of all mediastinal masses and include, in order of frequency, bronchogenic cysts, thymic cysts, pericardial and pleural cysts, oesophageal duplication cysts, meningoceles and thoracic duct cysts. Overall, just over one-third become symptomatic, either directly, as a result of pressure effects on surrounding structures (especially oesophageal and thymic cysts), or indirectly, as a result of secondary infection (bronchogenic cysts).
OESOPHAGUS

The oesophagus (Figs 55.13, 55.14; see also Figs 55.4, 55.7) is a muscular tube, typically 25 cm long, which connects the pharynx to the stomach. It begins in the neck, level with the lower border of the cricoid cartilage and the sixth cervical vertebra, and descends largely anterior to the vertebral column through the superior and posterior mediastina, passes through the diaphragm, level with the tenth thoracic vertebra, and ends at the gastric cardiac orifice level with the eleventh thoracic vertebra. Generally vertical in its course, the oesophagus has two shallow curves. It starts in the median plane, but inclines to the left as far as the root of the neck, gradually returns to the median plane near the fifth thoracic vertebra, and at the seventh thoracic vertebra deviates left again, before it pierces the diaphragm. The oesophagus also bends in an anteroposterior plane to follow the cervicothoracic curvatures of the vertebral column; it can also bend slightly to the right as it is pushed by the aorta before bending to the left to reach the oesophageal hiatus. It is the narrowest part of the alimentary tract (except for the vermiform appendix) and is constricted at the beginning (15 cm from the incisor teeth), where it is crossed by the aortic arch (22.5 cm from the incisor teeth), where it is crossed by the left principal bronchus (27.5 cm from the incisors) and as it passes through the diaphragm (40 cm from the incisors). These measurements are important clinically with regard to the passage of instruments along the oesophagus.
CERVICAL OESOPHAGUS

The cervical oesophagus (see Fig. 55.4) is posterior to the trachea and attached to it by loose connective tissue. The recurrent laryngeal nerves ascend on each side in or near the tracheo-oesophageal groove. Posteriorly are the vertebral column, longus colli and prevertebral layer of deep cervical fascia. Laterally on each side are the common carotid arteries and posterior part of the thyroid gland. In the lower neck, where the oesophagus deviates to the left, it is closer to the left carotid sheath and thyroid gland than it is on the right. The thoracic duct ascends for a short distance along its left side (see Fig. 55.5).
THORACIC OESOPHAGUS

The thoracic oesophagus (Figs 55.13, 55.14) is situated a little to the left in the superior mediastinum between the trachea and the vertebral column. It passes behind and to the right of the aortic arch to descend in the posterior mediastinum along the right side of the descending thoracic aorta. Below, as it inclines left, it crosses anterior to the aorta and enters the abdomen through the diaphragm at the level of the tenth thoracic vertebra. From above downwards, the trachea, right pulmonary artery, left main bronchus, pericardium (separating it from the left atrium) and the diaphragm are anterior. The vertebral column, longus colli, right posterior intercostal arteries, thoracic duct, azygos vein and the terminal parts of the hemiazygos and accessory hemiazygos veins, and, near the diaphragm, the aorta are posterior. A long recess of the right pleural sac lies between the oesophagus (in front) and the azygos vein and vertebral column (behind) in the posterior mediastinum.

In the superior mediastinum, the terminal part of the aortic arch, the left subclavian artery, thoracic duct, the left pleura and the recurrent laryngeal nerve are left lateral relations. In the posterior mediastinum, the oesophagus is related to the descending thoracic aorta and left pleura. The right pleura, and the azygos vein as it arches forwards above the right main bronchus to join the superior vena cava, are right lateral relations. Below the pulmonary roots, the vagus nerves descend in contact with the oesophagus, the right mainly behind and the left in front; the vagi subsequently unite to form a plexus around the oesophagus. Low in the posterior mediastinum, the thoracic duct is behind and to the right of the oesophagus; at higher levels the duct is posterior, crossing to the left of the oesophagus at about the level of the fifth thoracic vertebra and then ascending on the left. On the right of the oesophagus, just above the diaphragm, a small serous infracardiac bursa may occur; it represents the detached apex of the right pneumatoenteric recess.
ABDOMINAL OESOPHAGUS

The abdominal oesophagus is described in the section on Abdomen and Pelvis.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The cervical oesophagus is supplied by the inferior thyroid artery (see Ch. 28). The thoracic oesophagus is supplied by bronchial and oesophageal branches of the thoracic aorta (Fig. 55.14A). Four or five oesophageal branches arise from the anterior surface of the aorta and descend obliquely to the oesophagus, where they form a vascular chain that anastomoses above with the oesophageal branches of the inferior thyroid arteries, and below with ascending branches from the left phrenic and left gastric arteries.

Veins

Blood from the oesophagus drains into a submucous plexus and thence into a peri-oesophageal venous plexus from which oesophageal veins arise. Those from the thoracic oesophagus drain predominantly into the azygos veins and, to a lesser extent, the hemiazygos, intercostal and bronchial veins (Fig. 55.14B). Those from the cervical oesophagus drain into the inferior thyroid vein. The left gastric vein meets the lower oesophageal veins at the oesophageal opening in the lesser curvature and then drains into the portal vein.

Oesophageal varices

Cirrhosis or fibrosis of the liver affects the vascular tree within the liver and results in a decrease in hepatic vascular compliance. There is also an increased vascular tone, possibly reflecting a reduction in endothelial vasodilators such as nitric oxide. The portal resistance increases, leading to the formation of a collateral circulation, and there is a concomitant increase in the systemic and splanchnic blood flow. Portosystemic shunting of blood occurs between the short gastric coronary veins and the oesophageal veins, largely as the result of the dilatation of pre-existing embryonic channels.

Varices in the distal oesophagus are easily visible at endoscopy, because they are situated superficially in the lamina propria. The blood from the superficial veins drains into a superficial venous plexus, then into a deeper intrinsic venous plexus and finally into the perioesophageal veins via perforating veins. Bidirectional flow is normally possible in this region, a phenomenon that permits pressure changes during breathing and Valsalva manoeuvres. However, in portal hypertension, the valves within the perforating vessels become incompetent and blood flow is retrograde, causing dilatation of the deep intrinsic veins. The greater pressure within this region predisposes the varices to brisk and life-threatening bleeding. Treatment is directed towards controlling the formation of a collateral circulation and the obliteration of varices that are susceptible to bleeding, and
is achieved by paravariceal endoscopic injection of a sclerosant, which causes obliteration of the varices as a result of thrombus formation. Fibrosis is also induced within the mucosa, which reduces the formation of new collateral vessels. Alternatively, rubber bands may be applied in an attempt to ligate the varices. Bleeding from varices is associated with a mortality rate of 25%, reflecting the problems of rebleeding and underlying comorbidity.

**Lymphatic drainage**

The oesophagus has an extensive, longitudinally continuous submucosal lymphatic system, which presumably explains remote para-oesophageal lymphadenopathy in oesophageal carcinoma. Efferent vessels from the cervical oesophagus drain to the deep cervical nodes either directly or through the paratracheal nodes. Vessels from the thoracic oesophagus drain to the posterior mediastinal nodes and those from the abdominal oesophagus drain to the left gastric lymph nodes. Some may pass directly to the thoracic duct.
INNERVATION

The upper oesophagus is supplied by the branches of the recurrent laryngeal nerve and by postganglionic sympathetic fibres that reach it by travelling along the inferior thyroid arteries (Fig. 55.7) (see Ch. 28). The lower oesophagus is supplied by the oesophageal plexus, a wide-meshed autonomic network that surrounds the oesophagus below the level of the lung roots, and which contains a mixture of parasympathetic and sympathetic fibres.

Motor fibres to the striated and smooth muscle of the oesophageal wall travel in the vagus. Axons derived from neuronal cell bodies in the nucleus ambiguus travel via the recurrent laryngeal nerve and supply cricopharyngeus and the striated muscle of the upper one-third of the oesophagus. Axons with cell bodies in the dorsal nucleus of the vagus pass through the oesophageal plexus and supply the smooth muscle that makes up the lower two-thirds of the oesophagus, after local relay in the oesophageal wall. Other branches are given off by the vagus as it travels through the mediastinum, and pass directly to the oesophagus. The vagus also carries secretomotor fibres to mucous glands in the oesophageal mucosa, and visceral afferent (sensory) fibres to cell bodies in its inferior ganglion.

Vasomotor sympathetic fibres destined for the oesophagus arise from the upper four to six thoracic spinal cord segments. Those from the upper ganglia pass to the middle and inferior cervical ganglia, where they synapse on postganglionic neurones that give rise to axons which innervate the vessels of the cervical and upper thoracic oesophagus. Those from the lower ganglia pass either directly to the oesophageal plexus or to the coeliac ganglion (via the greater splanchnic nerve), where they synapse; postganglionic axons innervate the distal oesophagus. Afferent visceral pain fibres travel via the sympathetic fibres to the first four segments of the thoracic spinal cord: because these segments also receive afferents from the heart, it is sometimes difficult to distinguish between oesophageal and cardiac pain.
**MICROSTRUCTURE**

The tissues forming the thoracic oesophageal wall, from lumen outwards, are the mucosa (consisting of epithelium, lamina propria and muscularis mucosae), submucosa, muscularis externa and adventitia (Fig. 55.15; see Fig. 60.9).

*Fig. 55.15* The wall of the oesophagus. A stratified squamous, non-keratinizing epithelium lines the lumen (right), and submucosal glands (G) in the submucosa (SM) secrete mucus that lubricates the passage of food. (By permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)
Mucosa

The mucosa is thick. At the gastro-oesophageal junction, a jagged boundary line separates the greyish-pink, smooth, oesophageal mucosa from the reddish-pink gastric mucosa, which is covered by minute bulges and depressions. Throughout its length, the oesophageal lumen is marked by deep longitudinal grooves and ridges, which disappear when the lumen is distended, but obliterate the lumen at all other times.

Epithelium

The epithelium is a non-keratinized, stratified squamous epithelium, continuous with that of the oropharynx. In humans this protective layer is quite thick (300–500 µm) (Fig. 55.15), and is not affected by oesophageal distension. The boundary between the oesophageal epithelium and its lamina propria is distinct but markedly uneven, because tall connective tissue papillae invaginate the epithelial base, assisting in the anchorage of the epithelium to underlying tissues (Fig. 55.15). These papillae are permanent structures, also unaffected by oesophageal distension, and they are rich in blood vessels and nerve fibres. At the base of the epithelium there is a basal lamina, to which epithelial cells are attached by hemidesmosomes, as occurs in the oral mucosa.

Oesophageal epithelium is similar to other stratified squamous epithelia. It can be divided into a basal, proliferative layer, a parabasal layer of cells undergoing terminal differentiation, and a flattened layer of superficial cells or squames which retain their nuclei. The most superficial strata of cells contain a few keratohyalin granules, in addition to keratin filaments. The epithelial cell population is constantly renewed by mitosis in the cuboidal basal cells and the deepest parabasal cells. As they migrate towards the lumen, they become progressively polygonal and then more flattened, and are eventually desquamated at the epithelial surface. This sequence of events normally takes 2–3 weeks, and is markedly slower than in the stomach and intestine.

The epithelium is an effective protection against mechanical injury during swallowing because of its thickness and the presence of mucus at its surface. However, protection is limited by repeated exposure to the strongly acidic, protease-rich secretions of the stomach, as occurs abnormally during reflux. Normally, the lower oesophageal sphincter prevents reflux, but if reflux does occur, ulceration and fibrosis of the oesophageal wall, accompanied by considerable pain and difficulties in swallowing may ensue. Exposure to acid may also cause oesophageal epithelial metaplasia to a gastric-like mucosa (Barrett's mucosa), or to more overt neoplastic changes.
Langerhans cells

Langerhans cells are present in the oesophageal epithelium. They are immature dendritic cells and resemble those found in the epidermis. They perform similar antigen-processing and antigen-presenting roles, which are important in immunostimulation of naive T cells and mucosal defence.

Lamina propria

The oesophageal lamina propria contains scattered groups of lymphoid follicles (mucosa-associated lymphoid tissue), which are especially prominent near the gastro-oesophageal junction. Small tubular mucous glands occur in this region, and in the upper part of the oesophagus close to the pharynx.

Muscularis mucosae

The muscularis mucosae is composed mainly of longitudinal smooth muscle, and forms a thin sheet near the epithelium, the contours of which it follows closely. At the pharyngeal end of the oesophagus it may be absent or represented only by sparse, scattered bundles; below this it becomes progressively thicker. The longitudinal orientation of its cells changes to a more plexiform arrangement near the gastro-oesophageal junction.

Submucosa

The submucosa loosely connects the mucosa and the muscularis externa, and penetrates the longitudinal ridges of the oesophageal lumen. It contains larger blood vessels, nerves and mucous glands. Its elastic fibres are important in the reclosure of the oesophageal lumen after peristaltic dilatation.

Oesophageal glands

Oesophageal glands are small tubuloacinar glands lying in the submucosa, each group sending a single long duct through the intervening layers of the gut wall to the surface. They are composed mostly of mucous cells, although they also contain serous cells that secrete lysozyme. In the region close to the pharynx, and at the lower end close to the stomach, the glands are simpler in form and restricted to the lamina propria of the mucosa. The mucosal mucous glands of the abdominal oesophagus closely resemble the cardiac glands of the stomach, and are therefore called oesophageal cardiac glands.

Muscularis externa

The muscularis externa is up to 300 µm thick, and consists of the outer longitudinal and inner circular layers typical of the intestine. The longitudinal
fibres form a continuous coat around almost the entire length of the oesophagus, except that, posterosuperiorly, 3–4 cm below the cricoid cartilage, they diverge as two fascicles that ascend obliquely to the anterior aspect of the oesophagus. Here, they pass deep to the lower border of the inferior constrictor, and end in a tendon that is attached to the upper part of the ridge on the back of the cricoid lamina. The V–shaped space between these fascicles is filled by the circular muscle fibres of the oesophagus, which are thinly covered below by some decussating longitudinal fibres and above by the overlapping inferior constrictor. The longitudinal layer is generally thicker than the circular layer. Accessory slips of smooth muscle sometimes pass between the oesophagus and left pleura or the root of the left principal bronchus, trachea, pericardium or aorta, and are sometimes considered to fix the oesophagus to these structures. Superiorly, the circular fibres are continuous behind with the inferior pharyngeal constrictor. In front, the uppermost fibres are attached to the lateral margins of the tendon of the two longitudinal fasciculi of the oesophagus. Inferiorly, the circular muscle is continuous with the oblique layer of muscle fibres in the stomach wall. In the upper one-third of the oesophagus, the muscularis externa is formed by skeletal muscle; in the middle one-third, smooth muscle fascicles intermingle with striated muscle, and this increases distally such that the lower one-third contains only smooth muscle.
The oesophagus can be inspected visually by oesophagoscopy. This may be indicated in patients with persistent oesophageal symptoms such as atypical chest pain, dysphagia, odynophagia (painful swallowing) or symptoms of reflux. The procedure is performed with or without sedation. The endoscope is passed orally under direct vision with the patient in a lateral decubitus position. The endoscope is manoeuvred into the oesophageal inlet and the patient asked to swallow. Once the endoscope passes the oesophageal inlet, it is advanced slowly under direct vision and the mucosa carefully inspected. The mucosa normally appears whitish pink and changes at the lower oesophagus to a reddish mucosa at the squamocolumnar junction (Z line): this is closely related to the diaphragmatic hiatus, and displacement by more than 2 cm is indicative of a hiatus hernia. There may be slight extrinsic compression at the level of the aorta and occasionally at the left main bronchus.

Endoscopic transoesophageal ultrasound permits assessment of the oesophageal wall and para-oesophageal structures such as lymph nodes. This technique is more sensitive than CT scanning in detecting metastases in mediastinal lymph nodes, because it allows lymph nodes less than 10 mm in size to be assessed for possible malignant involvement. Normal lymph nodes cannot be easily identified by endoscopic ultrasound, because they have the same echogenicity characteristics as surrounding tissue; a hypoechoic or inhomogeneous pattern on ultrasound is considered more suspicious of malignancy. Endoscopic ultrasound-guided fine needle aspiration allows accurate diagnosis of lymph nodes, but only mediastinal nodes adjacent to the oesophagus can be fully evaluated. Transbronchial fine needle aspiration is an alternative approach for sampling mediastinal nodes, with lymph node choice based on CT findings. PET CT scanning is rapidly becoming the modality of choice for mediastinal nodal staging.

**Oesophageal rupture**

The majority of oesophageal ruptures are iatrogenic, and occur during the instrumentation of the oesophagus during simple endoscopy, endoscopic intervention and nasogastric tube placement. Other causes are traumatic, barotrauma, foreign bodies and oesophageal carcinoma. Barotrauma usually occurs with intense retching and vomiting. It usually causes a longitudinal tear in the posterior wall of the thoracic oesophagus. Overall, almost 60% of the perforations are located in the thoracic oesophagus, 25% in the cervical oesophagus and 15% in the abdominal oesophagus. Perforation in the cervical oesophagus occurs in the posterior wall, where it is at its thinnest, and often corresponds to an area of mucosa where there is no covering with muscle, and which is bordered by the pharyngeal inferior constrictor and cricopharyngeus. Mortality from oesophageal perforations is 20% and results
from mediastinitis and necrotizing infection. Presenting symptoms include thoracic pain, odynophagia, haematemesis, subacute surgical emphysema, tachycardia and breathlessness and, in the advanced case, septic shock. Early diagnosis (within 24 hours) and repair are associated with a better prognosis and a mortality rate of between 10% and 15%, whereas late diagnosis has a much greater mortality rate. For a perforation in the upper two-thirds of the thoracic oesophagus, a right thoracotomy in the fifth and sixth intercostal space is performed. The lower one-third of the oesophagus is approached through a left thoracotomy in the sixth and seventh intercostal space. The perforation is closed in layers after any necrotic tissue has been debrided.
BARIUM STUDIES

A double-contrast barium swallow with fluoroscopy enables anatomical and functional assessment of the oesophagus (see Fig. 55.18). A standard examination involves the patient swallowing a barium solution and gas granules, and images be taken in the erect, supine and prone recumbent positions. The upright posture fully dilates the oesophagus and is useful in evaluating any constrictions. The narrow tubular lumen of the oesophagus is slightly indented by the aortic arch and the left main bronchus. The supine view allows better evaluation of any motor dysfunction and varices, and moving into the prone position provokes underlying gastro-oesophageal reflux. Both repeating single digital images and cine loops of fluoroscopy can be obtained. The fluoroscopic images demonstrate defective opening of the pharyngeal oesophageal sphincter and the nature of the contractions in the body of the oesophagus. The cardio-oesophageal sphincter can be assessed in achalasia. Other abnormalities such as hiatus hernia and areas of narrowing or dilatation of the oesophagus may be demonstrated. Mucosal relief images are obtained once the bulk of the contrast media has passed into the stomach, and this provides fine mucosal detail. Cross-sectional imaging is usually used for the preoperative planning and staging of oesophageal tumours, and is of value in radiotherapy planning.

DEVELOPMENT

The development of the oesophagus is described in Chapter 35.

Tracheo-oesophageal fistula

Tracheo-oesophageal fistula is described in Chapter 59.

Oesophageal atresia

The vast majority of cases of oesophageal atresia occur in conjunction with a tracheo-oesophageal fistula, with an incidence of 1:3000–4000 births. There is a high incidence of associated congenital abnormalities such as cardiac, genitourinary, skeletal and other gastrointestinal anomalies. Prenatal diagnosis is unusual because of the lack of specific ultrasound features. The only prenatal indicators are polyhydramnios and, rarely, an absence of stomach gas; other clinical signs are the presence of a pharyngeal pouch on ultrasound. Postnatal clinical features are regurgitation of feeds; other symptoms, such as recurrent cough and choking spells, are related to the presence of a tracheo-oesophageal fistula. Corrective surgery is essential; overall survival is heavily influenced by the presence of associated cardiac anomalies.
OESOPHAGEAL SPHINCTERIC MECHANISMS

Radiological studies show that swallowed food stops momentarily in the gastric end of the oesophagus, before entering the stomach (see Fig. 55.18), suggesting the presence of a sphincter at this point. In the past there was much controversy as to the reason for this behaviour, because only slight thickening of the muscle coat has been found in humans. There is now ample physiological and clinical evidence that closure depends on two major mechanisms. The more important of these is the lower oesophageal sphincter, a specialized zone of circular smooth muscle surrounding the oesophagus at its transit through the diaphragm and for much of its short abdominal course. This region of the oesophagus is maintained under tonic contraction, except during swallowing, when it relaxes briefly to admit ingesta to the stomach, and during vomiting (see p. 954). It is controlled by the intramural plexuses of the enteric nervous system; in addition, the neural release of nitric oxide contributes to its relaxation. The second mechanism is a functional external sphincter provided by the crural diaphragm (usually the right crus), which encircles the oesophagus as it passes into the abdomen and is attached to it by the phreno-oesophageal ligament. Radiological, electromyographic and manometric analyses have shown that its muscular fibres contract around the oesophagus during inspiration and when intra-abdominal pressure is increased, thus helping to prevent gastro-oesophageal reflux, even when the lower oesophageal sphincter is inhibited experimentally with atropine. The relative importance of these two agents in the prevention of oesophageal reflux is still a matter for debate. Clinically, there is a good correlation between this condition and lower oesophageal sphincter dysfunction in some cases, whereas in others, failure of the diaphragmatic component, as seen in hiatus hernia, appears to be a major factor. The anatomical configuration of the gastro-oesophageal orifice may also play some part in these processes (see p. 954).

Swallowing

The oesophageal phase of swallowing is described in Chapter 33.

Vomiting

The lower oesophageal sphincter relaxes in the initial phase of vomiting at the same time as the crural fibres around the oesophagus relax. There is a subsequent rapid contraction of the diaphragm and abdominal muscles, with a resultant increase in intra-abdominal pressure.
OESOPHAGEAL DYSMOTILITY

The main disorders of oesophageal motility relate to disorders of the upper or lower oesophageal sphincters (discussed in detail in the section on upper gastro-oesophageal reflux) and achalasia. Problems with the upper oesophageal sphincter usually have a neurological aetiology. Brainstem disease impairs relaxation of cricopharyngeus (the lower oesophageal sphincter), leading to dysphagia of solids and liquids, with a tendency to aspirate; videofluoroscopy may demonstrate the abnormality.

Achalasia of the cardia is a primary motor disorder of the oesophagus in which there is failure of relaxation of the cardio-oesophageal sphincter and loss of peristalsis in the oesophageal body with degeneration of neuronal cell bodies in the myenteric nerve plexus. The clinical presentation is dysphagia, regurgitation of undigested food, retrosternal chest pain and occasional weight loss. A simple chest radiograph may show dilatation of the oesophagus and retention of food products as a mottled double-contoured mediastinal widening. Barium swallow shows a classical bird-beak appearance as a result of failure of relaxation of the lower oesophageal sphincter and an absence of peristalsis. Oesophageal manometry with pressure measurements confirms the diagnosis and demonstrates absent or impaired relaxation of the lower oesophageal sphincter. Treatment consists of pneumatic balloon dilatation during endoscopy or minimal-access surgical myotomy of the cardia. An alternative in frail patients is intrasphincteric injection of botulinum toxin. The advantages are lower morbidity and mortality, with a much lower risk of oesophageal perforation.

Diffuse oesophageal spasm may present with dysphagia and chest pain. It is characterized by abnormal oesophageal contractions on barium swallow, and produces simultaneous segmental contractions that obliterate the oesophageal lumen to produce a ‘corkscrew oesophagus’. Manometry also demonstrates titanic contractions of the oesophagus. Non-specific oesophageal motility disorder occurs with ageing (presbyoesophagus) and is characterized by a decreased incidence of normal, or even absent, peristalsis after swallowing. This may be accompanied by repetitive (tertiary) contractions and failure of relaxation of the lower oesophageal sphincter. Oesophageal dysmotility also includes oesophageal spasm and disorders caused by scleroderma or other connective tissue diseases, in which there is atrophy of smooth muscle and fibrous replacement in the submucosa and lamina propria.
GASTRO-OESOPHAGEAL REFLUX

Gastro-oesophageal reflux is described in Chapter 65, p. 1114.
HIATUS HERNIA

Hiatus hernia is described in Chapter 58.
MEDIASTINAL IMAGING

Mediastinal structures may be viewed using X-rays, CT and MRI.

NORMAL MEDIASTINAL CONTOURS ON FRONTAL CHEST RADIOGRAPH

In a standard posteroanterior chest radiograph the X-ray beam passes from back to the front of the chest. The standing patient breath-holds in full inspiration, and elevates and abducts the arms over the radiographic plate, movements which protract the scapulae and depress the medial ends of the clavicles to clear the peripheral lung fields and apices respectively. In this view the heart and large blood vessels appear as the ‘mediastinal silhouette’ (Fig. 55.16). Forming its left border, from above down, are the aortic arch (‘aortic knuckle’), sometimes with the left superior intercostal vein (‘aortic nipple’) visible, the pulmonary trunk and left ventricle. The descending aorta is projected as a continuous left paravertebral border all the way down to the diaphragm. The right border is delineated by the right brachiocephalic vein, superior vena cava, right atrium and thoracic inferior vena cava. A right paratracheal stripe (normally under 3 mm) is usually seen with the oval silhouette of the azygos arch at its lower margin. An accessory lung fissure, the azygos fissure, is seen rarely and extends from the apex of the lung to the right tracheobronchial angle. The azygos arch width should be no more than 5 mm, but may measure up to 10 mm in the third trimester of pregnancy as a result of a physiological blood volume increase. Enlargements or displacements of any of these structures accentuate the normal bulges on the borders of the mediastinal silhouette, thus an enlarged left auricle is seen between the pulmonary trunk and left ventricle. On both sides, opacities caused by pulmonary vessels associated with the roots of the lungs form hilar contours. In the upper thorax, the less dense projection of the trachea is visible in the median plane. The anterior junctional line, where the two lungs approximate above the heart, is sometimes visible. The posterior junctional line, which represents pleural apposition behind the oesophagus, is also sometimes seen: it projects up into the neck because of the obliquity of the thoracic inlet. The azygo-oesophageal recess is an area where a portion of the right lung is in contact with the azygos vein and the lateral wall line. The paraspinal lines are also visible parallel to the right and left margins of the thoracic spine.

2. Azygos vein.
3. Right atrial border.
4. Aortic arch.
5. Left ventricular border.
NORMAL MEDIASTINAL CONTOURS ON A LATERAL CHEST RADIOGRAPH

On a lateral view, the cardiac silhouette is seen above the anterior part of the diaphragm (Fig. 55.17). The anterior and posterior cardiac silhouettes are formed by the right ventricle and left atrium respectively. Behind is the retrocardiac space (posterior mediastinum) containing the descending thoracic aorta and the oesophagus: the oesophagus can be visualized with swallowed air or barium on a chest radiograph or fluoroscopically in the barium swallow examination (Fig. 55.18). Above, the less dense trachea and main bronchi are recognizable.
The aortic arch and large vessels anterior to the trachea produce faint shadows in the superior mediastinum. The brachiocephalic veins are visible as an extrapleural bulge directly behind the manubrium. The oesophagus is directly behind the trachea; the posterior paratracheal line, seen in the majority of lateral radiographs, represents the juxtaposition of the anterior oesophageal and posterior tracheal walls. The inferior vena cava is visible in
the majority of patients as it drains into the right atrium.
CT scans provide excellent cross-sectional views of the anatomy of the mediastinum and are complemented by MRI (Figs 55.19, 55.20). Intravenous contrast enhancement of the vessels improves the detail of the scan and improves distinction of blood vessels from lymph nodes and soft tissue opacities. Cross-sectional CT scanning is very useful in evaluating the mediastinal spaces, which include the pretracheal, subcarinal, right paratracheal and posterior tracheal spaces and aortopulmonary window: these areas are where mediastinal lymph node masses are located and hence of importance in the staging of lung cancer.
The pretracheal space, as seen in cross-section, is bordered by the trachea posteriorly, the superior vena cava and right brachiocephalic vein anteriorly,
and the descending aorta and the superior pericardial sinus to the left. The aortopulmonary window is located underneath the aortic arch and above the left pulmonary artery. The trachea forms its medial border and the lungs its lateral border. The right paratracheal space is in between the lung and the trachea on the anterolateral aspects, whereas the posterior tracheal space is formed between the lung and the posterior lateral aspect of the trachea. The subcarinal space is located below the carina and bounded by the two bronchi. On the right, the azygo-oesophageal recess is located posterior to the subcarinal space and on the left side is the oesophagus. All these areas are in direct continuity with each other and are traversed during cervical mediastinoscopy.

The junctional areas are where the two lungs approach each other. The anterior or prevascular junction is anterior to the great vessels and posterior to the chest wall, and between the two lungs. The left brachiocephalic vein, highest mediastinal nodes, thymus and phrenic nerves are located in the anterior junction. The posterior junction is an area posterior to the trachea and is where the lungs lie close to each other. The paraspinal area is a space between the lateral margins of the spine and the lungs. The intercostal vessels, sympathetic chain and ganglia, and small lymph nodes are located within the paraspinal space. The retrocrural space, between the diaphragmatic crura and the vertebral bodies, is traversed by the aorta, azygos and hemiazygos veins, the thoracic duct, intercostal arteries, sympathetic chains and splanchnic nerves.
REFERENCES

CHAPTER 56 – Heart and great vessels

PERICARDIUM

The pericardium contains the heart and the juxtacardiac parts of its great vessels. It consists of two components, the fibrous and the serosal pericardium. The fibrous pericardium is a sac made of tough connective tissue, completely surrounding the heart without being attached to it. This fibrous sac develops by a sequential process of cavitation of the embryonic body wall by expansion of the secondary pleural cavity. Thus its lateral walls are clothed externally by parietal mediastinal pleura. The serosal pericardium consists of two layers of serosal membrane, one inside the other: the inner (visceral) one adheres to the heart and forms its outer covering known as the epicardium, whereas the outer (parietal) one lines the internal surface of the fibrous pericardium. The two serosal surfaces are apposed and separated by a film of fluid. This allows movement of the inner membrane and the heart adhering to it, except at the arterial and venous areas of the pericardium where the two serosal membranes merge. These last constitute two parietovisceral lines of serosal reflexion. The separation of the two membranes of the serosal pericardium creates a narrow space, the pericardial cavity, which provides a complete cleavage between the heart and its surroundings and so allows it some freedom to move and change shape.

FIBROUS AND SEROSAL PERICARDIUM

The fibrous pericardium is compact collagenous fibrous tissue. The serosal pericardium is a single layer of flat cells on a thin subserosal layer of connective tissue, which blends with the fibrous pericardium in the parietal membrane and with the interstitial myocardial tissue in the visceral membrane. On the cardiac side, the subserosal layer contains fat, especially along the ventricular side of the atrioventricular groove, the inferior cardiac border and the interventricular grooves. The main coronary vessels and their larger branches are embedded in this fat; the amount is related to the general extent of body fat and gradually increases with age.

Fibrous pericardium

The fibrous pericardium is roughly conical and clothes the heart. Superiorly, it is continuous exteriorly with the adventitia of the great vessels; inferiorly it is attached to the central tendon of the diaphragm and a small muscular area of its left half. Above, the fibrous pericardium not only blends externally with the great vessels, but is continuous with the pretracheal fascia. Anteriorly, it is also attached to the posterior surface of the sternum by superior and inferior sternopericardial ligaments, although the extent of these ‘ligaments’ is extremely variable, and the superior one is often undetectable. The pericardium is securely anchored by these connections and maintains the general thoracic position of the heart, serving as the ‘cardiac seat belt’.

Anteriorly, the fibrous pericardium is separated from the thoracic wall by the lungs and the pleural coverings. However, in a small area behind the lower left half of the body of the sternum and the sternal ends of left fourth and fifth costal cartilages, the pericardium is in direct contact with the thoracic wall. Until it regresses, the lower end of the thymus is also anterior to the upper pericardium. The principal bronchi, oesophagus, oesophageal plexus, descending thoracic aorta and posterior parts of the mediastinal surface of both lungs are posterior relations. Laterally are the pleural
coverings of the mediastinal surface of the lungs. The phrenic nerve, with its accompanying vessels, descends between the fibrous pericardium and mediastinal pleura on each side. Inferiorly, the pericardium is separated by the diaphragm from the liver and fundus of the stomach.

The aorta, superior vena cava, right and left pulmonary arteries and the four pulmonary veins all receive extensions of the fibrous pericardium. The inferior vena cava, which traverses the central tendon, has no such covering.

**Serosal pericardium**

The serosal pericardium is a closed sac within the fibrous pericardium, and has a visceral and a parietal layer. The visceral layer, or epicardium, covers the heart and great vessels and is reflected into the parietal layer, which lines the internal surface of the fibrous pericardium. The reflections of the serosal layer are arranged as two complex ‘tubes’: the aorta and pulmonary trunk are enclosed in one, and the superior and inferior venae cavae and the four pulmonary veins in the other. The tube surrounding the veins has the shape of an inverted J. The cul-de-sac within its curve is behind the left atrium and is termed the oblique sinus. The transverse sinus is a passage between the two pericardial ‘tubes’ (Fig. 56.1). It has the aorta and pulmonary trunk in front and the atri and great veins behind (see Fig. 56.2B,D). The arrangement of the oblique and transverse sinuses, along with that of the main ‘principal’ cavity, is further affected by the development of complex three-dimensional pericardial recesses between adjacent structures. These recesses can be grouped according to the siting of their orifices or ‘mouths’. From the principal pericardial cavity, the postcaval recess projects towards the left behind the atrial termination of the superior vena cava. It is limited above by the right pulmonary artery and below by the upper right pulmonary vein. Its mouth opens superolaterally to the right. The right and left pulmonary venous recesses each project medially and upwards on the back of the left atrium between the superior and inferior pulmonary veins on each side, indenting the side walls of the oblique sinus. The superior aortic recess extends from the transverse sinus. From its mouth, located inferiorly, it ascends posterior to, then to the right of, the ascending aorta and ends at the level of the sternal angle. The inferior aortic recess, also extending from the transverse sinus, is a diverticulum descending from a superiorly located mouth to run between the lower ascending part of the aorta and the right atrium. The left pulmonary recess, with its mouth under the fold of the left vena cava, passes to the left between the inferior aspect of the left pulmonary artery and the upper border of the superior left pulmonary vein. The right pulmonary recess lies between the lower surface of the proximal part of the right pulmonary artery and the upper border of the left atrium.
Fig. 56.1 Interior of the pericardial sac after section of the large vessels at their cardiac origin and removal of the heart (seen from the front). See text for named recesses of the general serosal pericardial cavity and its transverse sinus.

(From Sobotta 2006.)
A triangular fold of serosal pericardium is reflected from the left pulmonary artery to the subjacent upper left pulmonary vein as the fold of the left superior vena cava. It contains a fibrous ligament, a remnant of the obliterated left common cardinal vein (left duct of Cuvier). This ligament descends anterior to the left pulmonary hilum from the upper part of the left superior intercostal vein to the back of the left atrium, where it is continuous with the oblique vein of the left atrium. The left common cardinal vein may persist as a left superior vena cava which then replaces the oblique vein of the left atrium and empties into the coronary sinus. When both common cardinal veins persist as right and left superior venae cavae, the transverse anastomosis between them, which normally forms the left brachiocephalic vein, may be small or absent. When there is a left superior vena cava, it is joined by the left superior intercostal vein.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The arteries of the pericardium are derived from the internal thoracic and musculophrenic arteries and the descending thoracic aorta. The veins are tributaries of the azygos system.
INNERVATION

The pericardium is innervated by the vagus, together with phrenic nerves and the sympathetic trunks (see Fig. 56.20; see Fig. 58.3). Pericardial pain is typically a sharp severe substernal pain. It may be exacerbated by lying back or on the left side and relieved by leaning forward. It occasionally radiates to the upper border of trapezius.

**Fig. 56.20** The human cardiac plexus: its source from the cervical parts of the vagus nerves and sympathetic trunks and its extensions, the pulmonary, atrial and coronary plexuses. Note the numerous junctions between sympathetic and parasympathetic (vagal) branches that form the plexus.
CARDIAC TAMPONADE

Cardiac tamponade is external compression of the heart usually caused by accumulation of fluid in the pericardial space. This causes compression of the right atrium and reduces venous return, which reduces cardiac output. It may occur after trauma, proximal extension from a dissecting aortic aneurysm or cardiac surgery. Patients develop hypotension and circulatory collapse. Emergency treatment involves first relieving the tamponade by percutaneous pericardial aspiration, followed by surgery to address the underlying cause. Echocardiography can be useful in assessing tamponade and is also useful in guiding percutaneous pericardial aspiration. Surgery is via a subxiphoid incision or a left anterior thoracotomy.
HEART

The microstructure of cardiac muscle is described in detail in Chapter 6.

GENERAL ORGANIZATION

The heart is a pair of valved muscular pumps combined in a single organ (Fig. 56.2A–D). Although the fibromuscular framework and conduction tissues of these pumps are structurally interwoven, each pump (the so-called ‘right’ and ‘left’ hearts) is physiologically separate, and is interposed in series at different points in the double circulation. Despite this functional disposition in series, the two pumps are usually described topographically in parallel.

Of the four cardiac chambers, the two atria receive venous blood as weakly contractile reservoirs for final filling of the two ventricles, which then provide the powerful expulsive contraction that forces blood into the main arterial trunks.

The right heart starts at the right atrium, and receives the superior and inferior venae cavae together with the main venous inflow from the heart itself via the coronary sinus. This systemic venous blood traverses the right atrioventricular orifice, guarded by the tricuspid valve, to enter the inlet component of the right ventricle. Contraction of the ventricle, particularly its apical trabecular component, closes the tricuspid valve and, with increasing pressure, ejects the blood through the muscular right ventricular outflow tract into the pulmonary trunk. The blood then flows through the pulmonary vascular bed, which has a relatively low resistance. Changes in pressure, time relations and valvular events are described below. Many structural features of the ‘right heart’, including its overall geometry, myocardial architecture and the construction and the relative strengths of the tricuspid and pulmonary valves, accord with this low resistance, being associated with comparatively low changes in pressure.

The left heart starts at the left atrium, which receives all the pulmonary inflow of oxygenated blood and some coronary venous inflow. It contracts to fill the left ventricle through the left atrioventricular orifice guarded by its mitral valve. The valve is the entry to the inlet of the left ventricle. Ventricular contraction rapidly increases the pressure in the apical trabecular component, closing the mitral valve and opening the aortic valve, enabling the ventricle to eject via the left ventricular outflow tract into the aortic sinuses and the ascending aorta, and thence to the entire systemic arterial tree, including the coronary arteries. This vast vascular bed presents a high peripheral resistance that, with large metabolic demands (especially the sustained requirements of the cerebral tissues), explains the more massive structural organization of the ‘left heart’. The ejection phase of the left ventricle is shorter than that of the right, but its fluctuations in pressure are very much greater. Because of its contrasting functional demands, the heart is far from a simple pair of (structurally combined) parallel pumps, even though the right and left ventricles must deliver more or less the same volume with each contraction. The heart has a complicated, spiral, three-dimensional organization which is markedly skewed when compared with the planes of the body. Terms such as ‘left’ and ‘right’, ‘anterior’ and ‘posterior’, ‘superior’ and ‘inferior’, therefore, do not always assist the descriptions of cardiac anatomy. Another potential source of confusion is the usual study of isolated whole or dissected hearts, with the subsequent difficulty in relating details to the heart as it is positioned within the body. The following preliminary description emphasizes such difficulties in order to
circumvent certain misconceptions, before proceeding to an account of more detailed structure.

The right heart, while forming the right aspect or ‘border’, follows a gentle curve and covers most of the anterior aspect of the left heart (except for a left-sided strip including the apex). Thus the right heart forms the largest part of the anterior surface, its outflow tract ascending until it terminates on the left side of the outflow tract from the left ventricle. The sites of the tricuspid and pulmonary valves are widely separated and on different planes, the flat cavity of the right ventricle, which is crescentic in its section, splaying out between them. Conversely, the left heart (except the left-sided strip mentioned above) is largely posterior in position and when viewed from the front is obscured by the chambers of the right heart. The inlet to the left ventricle, which contains the mitral valve, is very close to its outlet (the aortic valve), the two being embraced by the wide tract linking inlet and outlet components of the right ventricle. The planes of the left ventricular orifices, although relatively inclined, are more nearly co-planar than those of the right. The left ventricular cavity is narrow and conical, and its tip occupies the cardiac apex. Most of the base of the heart is made up of the left atrium.

Cardiac size, shape and external features

The heart is a hollow, fibromuscular organ of a somewhat conical or pyramidal form, with a base, apex and a series of surfaces and ‘borders’. Enclosed in the pericardium, it occupies the middle mediastinum between the lungs and their pleural coverings (Fig. 56.1). It is placed obliquely behind the body of the sternum and the adjoining costal cartilages and ribs. Approximately one-third of the mass lies to the right of the midline.

An average adult heart is 12 cm from base to apex, 8–9 cm at its broadest transverse diameter and 6 cm anteroposteriorly. Its weight varies from 280 to 340 g (average 300 g) in males and from 230 to 280 g (average 250 g) in females. Cardiac weight is 0.45% of body weight in males and 0.40% in females. Adult weight is achieved between the ages of 17 and 20 years. The oblique position of the heart may be emphasized by comparing it to a rather deformed pyramid, with the base facing posteriorly and to the right, and the apex anteriorly and to the left. A line from the apex to the approximate centre of the base, projected posterolaterally, emerges near the right midscapular line. Some surfaces of the cardiac ‘pyramid’ are flat, others more or less convex, these aspects merging along rather ill-defined ‘borders’. Precise definition of surfaces and intervening ‘borders’ is, therefore, difficult. In the account that follows, official nomenclature (Terminologia Anatomica 1998) and more generally used terms from clinical practice are given as alternatives. The heart is described as having a base and apex, its surfaces being designated as sternocostal (anterior), diaphragmatic (inferior) and right and left (pulmonary). Its borders are termed upper, inferior (‘acute’ margin or border) and left (‘obtuse’ margin or border). Some name the right surface a ‘border’, despite its extent. One avoidable source of confusion is the use of ‘posterior’, which can be replaced with the unambiguous term ‘diaphragmatic’. If posterior is to be used for a cardiac surface, it should be reserved for the base. (However, compounding this difficulty, there are a number of different usages of the term ‘cardiac base’.)

The heart is placed obliquely in the thorax. The atrial and ventricular septal structures
are virtually in line, but inclined forwards and to the left at 45° to a sagittal plane. The planes of the mitral and tricuspid valves, although vertical and not precisely co-planar, are broadly at right angles to the septal plane. The right atrium, therefore, is not only to the right, but also anterior and inferior to the left atrium. It is also partly anterior to the left ventricle, an important atrioventricular septum intervening. The right ventricle forms most of the anterior aspect of the ventricular mass (Fig. 56.3), only its inferior end is to the right of the left ventricle, its upper left extremity (pulmonary orifice) is to the left and superior relative to the aortic valve. The left atrium forms most of the posterior aspect of the heart, whereas the left ventricle is only prominent inferiorly, running along the left margin to reach the apex. The atria are essentially right of and posterior to their respective ventricles. These general dispositions are of the greatest importance in planning or interpreting radiographs, scans, angiograms and echocardiograms.
Grooves on the cardiac surface

The division of the heart into four chambers produces boundaries that are visible externally as grooves (sulci). Some are deep and obvious and contain prominent structures. Others are less distinct, even barely perceptible, and are sometimes obscured, in part, by the major structures that cross them. The interatrial groove is a shallow groove separating the two atria. The lateral limits are defined by the borders of the atria. The atroventricular (coronary) groove (or sulcus) separates the atria from the ventricles. This groove, containing the main trunks of the coronary arteries, is oblique. It descends to the right on the sternocostal surface, separating the right atrium (and its auricle or appendage) from the oblique right margin of the right ventricle and its infundibulum. Its upper left part is obliterated where it is crossed by the pulmonary trunk and, behind this, the aorta, from which the coronary arteries originate. Continuing to the left, the groove curves around the ‘obtuse’ margin and descends to the right, separating the atrial base from the diaphragmatic surface of the ventricles (Fig. 56.2A,D). This diaphragmatic part of the atroventricular groove then curves around the ‘acute’ margin at its lower right end to become confluent with the sternocostal part. Thus the groove passes from high on the left to low on the right, with the diaphragmatic part being a little to the left of the sternocostal. A section that includes the atroventricular groove is at 45° to the sagittal plane and at a greater but variable angle to the transverse and coronal planes. It approximately traverses the lines of attachment of the atroventricular valves and (even less precisely) those of the aortic and pulmonary valves. A line at right angles to the centre of this plane will descend forwards and leftwards to the cardiac apex.

Internally, the ventricles are separated by the septum. The mural margins of the septum correspond to the anterior and inferior (diaphragmatic) interventricular grooves. The anterior groove, seen on the sternocostal cardiac surface, is near and almost parallel to the left ventricular obtuse margin. On the diaphragmatic surface, the groove is closer to the midpoint of the ventricular mass. The interventricular grooves extend from the atroventricular groove to the apical notch on the acute margin, which is a little to the right of the true cardiac apex.

Cardiac base, apex, surfaces and borders

Posterior aspect of the heart

The true cardiac base is somewhat quadrilateral, with curved lateral extensions. It faces back and to the right, separated from the thoracic vertebrae (fifth to eighth in the recumbent, sixth to ninth in the erect posture) by the pericardium, right pulmonary veins, oesophagus and aorta. It is formed mainly by the left atrium, and only partly by the posterior part of the right atrium (Fig. 56.2B,D). It extends superiorly to the
bifurcation of the pulmonary trunk and inferiorly to the posterior part of the atroventricular groove, which contains the coronary sinus and branches of the coronary arteries. It is limited to the right and left by the rounded surfaces of the corresponding atria. These are separated by the shallow interatrial groove. The point of junction of the atroventricular, interatrial and posterior interventricular grooves is termed the crux of the heart. Two pulmonary veins on each side open into the left atrial part of the base, whereas the superior and the inferior vena cava open into the upper and lower parts of the right atrial basal region. The area of the left atrium between the openings of right and left pulmonary veins forms the anterior wall of the oblique pericardial sinus (Fig. 56.1). This description of the anatomical base reflects the usual position of the heart in the thorax. Some confusion is produced by other current usages of the term 'base'. It is often applied to the segment of the atroventricular and ventriculoarterial junctions seen after dissections through the atroventricular groove. This area is better termed the base of the ventricles. In clinical practice, auscultation in or near the parasternal parts of the second intercostal spaces is often described as occurring at the clinical 'base', to make the contrast with the clinical 'apex'. Such descriptions, while less than perfect anatomically, will almost certainly persist.

Anatomical apex of the heart

This is the apex of the conical left ventricle, which is directed down, forwards and to the left. It is overlapped by the left lung and pleura. The apex is located most commonly behind the fifth left intercostal space, near or a little medial to the midclavicular line.

Anterior, sternocostal surface of the heart

Facing forwards and upwards, the anterior surface has an acute right and a more gradual left convexity (Fig. 56.3). It consists of an atrial area above and to the right, and a ventricular part below and to the left of the atroventricular groove. The atrial area is occupied almost entirely by the right atrium. The left atrium is largely hidden by the ascending aorta and pulmonary trunk. Only a small part of the left appendage projects forwards to the left of the pulmonary trunk. Of the ventricular region, about one-third is made up by the left and two-thirds by the right ventricle. The site of the septum between them is indicated by the anterior interventricular groove. The sternocostal surface is separated by the pericardium from the body of the sternum, the sternocostal muscles and the third to the sixth costal cartilages. Because of the bulge of the heart to the left, more of this surface is behind the left costal cartilages than behind the right ones. It is also covered by the pleural membranes and by the thin anterior edges of the lungs, except for a triangular area at the cardiac incisure of the left lung. The lungs and their pleural coverings are variable in their degree of overlap of the heart.

Inferior, diaphragmatic surface of the heart

Largely horizontal, the inferior surface of the heart slopes down and forwards a little towards the apex (Fig. 56.2B,D). It is formed by the ventricles (chiefly the left) and rests mainly upon the central tendon but also, apically, on a small area of the left muscular part of the diaphragm. It is separated from the anatomical base by the atroventricular groove and is traversed obliquely by the posterior interventricular groove.
Left surface of the heart

Facing up, back and to the left, the left surface consists almost entirely of the obtuse margin of the left ventricle, but a small part of the left atrium and its auricle contribute superiorly. Convex and widest above, where it is crossed by the atrioventricular groove, it narrows to the cardiac apex. It is separated by the pericardium from the left phrenic nerve and its accompanying vessels, and by the left pleura from the deep concavity of the left lung.

Right surface of the heart

The right surface is rounded and formed by the right atrial wall. It is separated from the mediastinal aspect of the right lung by the pericardium and the pleural coverings. Its convexity merges below into the short intrathoracic part of the inferior vena cava and above into the superior vena cava. The sulcus terminalis (terminal groove) is a prominent landmark between the true atrial and the venous components of the right atrium, curving approximately along the junction of the sternocostal and right surfaces.

Upper border of the heart

This is atrial (mainly the left atrium). Anterior to it are the ascending aorta and the pulmonary trunk (Fig. 56.1). At its extremity, the superior vena cava enters the right atrium.

Right border of the heart

Corresponding to the right atrium, the profile of the right border is slightly convex to the right and it approaches the vertical.

Inferior border of the heart

Also known as the acute margin of the heart, the inferior border is sharp, thin and nearly horizontal. It extends from the lower limit of the right border to the apex and it is formed mainly by the right ventricle, with a small contribution from the left ventricle near the apex.

Left border of the heart

Also known as the obtuse margin, the left border separates the sternocostal and left surfaces. It is round and mainly formed by the left ventricle but, to a slight extent superiorly, is formed by the auricle of the left atrium. It descends obliquely, convex to the left, from the auricle to the cardiac apex.

Right atrium

General and external features

The interatrial septum (or atrial septum) is oblique, so the right atrium is both anterior and to the right of the left atrium (Fig. 56.2A–D), also extending inferior to it. Its walls form the right upper sternocostal surface, the convex right (pulmonary surface) and a little of the right side of the anatomical base. The superior vena cava opens into its dome and the inferior vena cava into its lower posterior part (Fig. 56.2B,D). An extensive muscular pouch, the auricle, projects anteriorly to overlap the right side of
the ascending aorta. The auricle is a broad, triangular structure and has a wide junction with the true atrial component of the atrium (Fig. 56.2A,C). The junction between the venous part (sinus venosus) and the atrium proper is marked externally by a shallow groove, the sulcus terminalis, extending between the right sides of the openings of the two venae cavae. The sulcus terminalis corresponds, internally, to the terminal crest (crista terminalis) which is the site of origin of the extensive pectinate muscles that arise serially at right angles from the crest. Posteriorly, the vertical interatrial groove descends to the crux.

Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung, from which it is separated by pleura and pericardium. Laterally, the atrium is also related to the mediastinal surface of the right lung, but anterior to its hilum and separated from it by the pleura, right phrenic nerve and pericardiacophrenic vessels and pericardium. Posteriorly and to the left, the atrial septum and the surrounding infolded atrial walls separate the right from the left atrium (the mural infolding is indicated by an extensive interatrial groove). Posteriorly and to the right are the right pulmonary veins. Medially are the ascending aorta and, to a lesser extent, the root of the pulmonary trunk and its bifurcation.

**Interior surface**

The interior surface of the right atrium can be divided into three regions: a smooth-walled venous component posteriorly that leads, anteriorly, to the vestibule of the tricuspid valve and the auricle (Fig. 56.4A,B). The wall of the vestibule is smooth, but its junction with the auricle is ridged all around the atrioventricular junction. The smooth-walled part receives the opening of the venae cavae and the coronary sinus. It represents the venous component (sinus venosus) of the developing heart. The wall of the vestibule has a ridged surface and that of the auricle is trabeculated. Both are derived from the embryonic atrium proper.
The superior and inferior venae cavae open into the venous component. The superior vena cava returns blood from head, neck and upper limb through an orifice that faces inferoanteriorly and has no valve, and also receives blood from the chest wall and the oesophagus via the azygos system. The inferior vena cava is larger than its superior counterpart: it drains blood from all structures below and including the diaphragm into the lowest part of the atrium near the septum. Anterior to its orifice is a flap-like valve, the Eustachian valve or valve of the inferior vena cava (Fig. 56.4A,B). Of varying size, this valve is found along the lateral, or right, margin of the vein. When traced inferiorly, it runs into the sinus septum (see below), where it is contiguous with the valve of the coronary sinus. The lateral part of the Eustachian valve becomes continuous with the
lower end of the terminal crest. The valve is a fold of endocardium enclosing a few muscular fibres. It is large during fetal life, when it serves to direct richly oxygenated blood from the placenta through the foramen ovale of the atrial septum into the left atrium. The valve varies markedly in size in postnatal life; it is sometimes cribriform or filamentous but often is absent. A particularly prominent recess, behind the Eustachian valve, is seen posteroinferiorly relative to the ostium of the coronary sinus.

The coronary sinus opens into the venous atrial component between the orifice of the inferior vena cava, the fossa ovale and the vestibule of the atroventricular opening (Fig. 56.4A,B). The coronary sinus is often guarded by a thin, semicircular valve that covers the lower part of the orifice (Thebesius' valve, also known as the Thebesian valve). The upper limb of this valve joins the Eustachian valve; a tendinous structure, the tendon of Todaro, runs from this commissure into the sinus septum, which is the septum between the coronary sinus and the fossa ovale. The tendon of Todaro runs forwards to insert into the central fibrous body and is one of the landmarks of the triangle of Koch (see below). The ostium of the coronary sinus forms a prominent landmark in the right atrium. The sinus itself lies within the left atroventricular groove (Fig. 56.2B,D), and is the conduit for return of most of the venous blood from the heart, although some atrial veins drain directly to the right or left atrial chambers. The coronary sinus begins at the point where the oblique vein of the left atrium joins the great cardiac vein. The sinus receives the middle and small cardiac veins close to its junction with the right atrium.

Several small venous ostia, draining the minimal atrial veins, are found scattered around the atrial walls. They return a small fraction of blood from the heart, and are most numerous on the septal aspect. The anterior cardiac veins and, sometimes, the right marginal vein may enter the atrium through larger ostia.

The atrium proper and the auricle are separated from the venous sinus by the crista terminalis. This smooth, muscular ridge begins on the upper part of the septal surface and, passing anterior to the orifice of the superior vena cava, skirts its right margin to reach the right side of the orifice of the inferior vena cava. It marks the site of the right venous valve of the embryonic heart, and corresponds externally to the terminal groove. The sinus-atrial node is located within the superior part of the groove, lateral to and extending below the orifice of the superior vena cava (Fig. 56.4A,B).

The pectinate muscles (musculi pectinati), almost parallel muscular ridges, extend anterolaterally from the terminal crest and reach into the auricle, where they form several trabeculations.

The septal wall presents the fossa ovale, an oval depression above and to the left of the orifice of the inferior vena cava. Its floor is the primary atrial septum, the septum primum. The rim of the fossa is prominent and, although often said to represent the edge of the so-called septum secundum, in reality it is merely the infolded walls of the atrial chambers. It is most distinct above and in front of the fossa, and is usually deficient inferiorly. A small slit is sometimes found at the upper margin of the fossa, ascending beneath the rim to communicate with the left atrium. This represents failure of obliteration of the fetal foramen ovale, which remains patent in up to one-third of all normal hearts.

Anteroinferior in the right atrium is the large, oval vestibule leading to the orifice of the
tricuspid valve. A triangular zone, the triangle of Koch, is defined between the attachment of the septal cusp of the tricuspid valve, the anteromedial margin of the ostium of the coronary sinus, and the round, collagenous, palpable, subendocardial tendon of Todaro (Fig. 56.4A,B). The triangle is a landmark of particular surgical importance, indicating the site of the atrioventricular node and its atrial connections. Anterosuperior to the insertion of the tendon of Todaro, the septal wall is formed by the atrioventricular component of the membranous septum, intervening between the right atrium and subaortic outlet of the left ventricle (Fig. 56.5). The atrial wall bulges anterosuperiorly above the membranous septum. This area is the aortic mound (torus aorticus) and marks the location of the non-coronary sinus of the aorta with its enclosed valvular cusp.
Right ventricle

The right ventricle extends from the right atrioventricular (tricuspid) orifice nearly to the cardiac apex. It then ascends to the left to become the infundibulum, or conus arteriosus, reaching the pulmonary orifice and supporting the cusps of the pulmonary valve. Topographically, the ventricle possesses an inlet component which supports and surrounds the tricuspid valve; a coarsely trabeculated apical component; and a muscular outlet or infundibulum, which surrounds the attachments of the cusps of the pulmonary valve.

External features

The convex anterosuperior surface of the right ventricle makes up a large part of the sternocostal aspect of the heart, and is separated from the thoracic wall only by the pericardium (Fig. 56.2A–D). The left pleura and, to a lesser extent, the anterior margin of the left lung are interposed above and to the left. The inferior surface is flat and is related mainly, with the interposition of the pericardium, to the central tendon and a small adjoining muscular part of the diaphragm. The left and posterior wall is the ventricular septum. This is slightly curved and bulges into the right ventricle so that, in sections across the cardiac axis, the outline of the right ventricle is crescentic. A delicate collagenous band, the tendon of the infundibulum (conus ligament), is believed by some to connect the pulmonary muscular infundibulum posteriorly to the root of the aorta. The wall of the right ventricle is significantly thinner (3–5 mm on average) than that of the left, the ratio of the thickness of the two walls usually being 1:3.

Internal features

The inlet and outlet components of the ventricle, supporting and surrounding the cusps of the tricuspid and pulmonary valves respectively, are separated in the roof of the ventricle by the prominent supraventricular crest (crista supraventricularis) (Fig. 56.4A). The crest is a thick, muscular, highly arched structure, extending obliquely forwards and to the right from a septal limb high on the interventricular septal wall to a mural or parietal limb on the anterolateral right ventricular wall. The posterolateral aspect of the crest provides a principal attachment for the anterosuperior cusp of the tricuspid valve. The septal limb of the crest may be continuous with, or embraced by, the septal limbs of the septomarginal trabecula. The inlet and outlet regions extend apically into and from the prominent coarsely trabeculated component of the ventricle. The inlet component is itself also trabeculated, whereas the outlet component (or infundibulum) has predominantly smooth walls. The trabeculated appearance is caused by a myriad of irregular muscular ridges and protrusions, which are known collectively as trabeculae carneae, and are lined by endocardium. These protrusions and intervening grooves impart great variation in wall thickness; the protrusions vary in extent from mere ridges to trabeculae, which are fixed at both ends but otherwise free. Other conspicuous protrusions are the papillary muscles, which are inserted at
one end onto the ventricular wall and are continuous at the other end with collagenous
cords, the chordae tendineae, inserted on the free edge and elsewhere on the free
aspect of the atrioventricular valves. One protrusion in the right ventricle, the
septomarginal trabecula or septal band, is particularly prominent. It reinforces the
septal surface where, at the base, it divides into limbs that embrace the
supraventricular crest. Towards the apex, it supports the anterior papillary muscle of
the tricuspid valve and, from this point, crosses to the parietal wall of the ventricle as
the 'moderator band' (this alternative name records an old idea that the septomarginal
trabecula prevents overdistension of the ventricle). A further series of prominent
trabeculae, the septoparietal trabeculations, extend from its anterior surface and run
onto the parietal ventricular wall. The smooth-walled outflow tract, or infundibulum
(conus arteriosus), ascends to the left above the septoparietal trabeculations and
below the arch of the supraventricular crest to the pulmonary orifice.

Tricuspid valve

The atrioventricular valvular complex, in both right and left ventricles, consists of the
orifice and its associated anulus, the cusps, the supporting chordae tendineae of
various types and the papillary muscles.

Harmonious interplay of all these, together with the atrial and ventricular myocardial
masses, depends on the conduction tissues and the mechanical cohesion provided by
the fibroelastic cardiac skeleton. All parts change substantially in position, shape,
angulation and dimensions during a single cardiac cycle.

Tricuspid valvular orifice

The tricuspid valve orifice is best seen from the atrial aspect and measures on
average 11.4 cm in circumference in males and 10.8 cm in females. It has a clear line
of transition from the atrial wall or septum to the lines of attachment of the valvular
cusps. Its margins are not precisely in a single plane. It is almost vertical, but at 45° to
the sagittal plane and slightly inclined to the vertical, such that it ‘faces’ (on its
ventricular aspect) anterolaterally to the left and somewhat inferiorly (Fig. 56.6).
Roughly triangular, its margins are described as anterosuperior, inferior and septal,
corresponding to the lines of attachment of the valvular cusps.
The connective tissues around the orifice of the atrioventricular valves separate the atrial and ventricular myocardial masses completely, except at the point of penetration of the atrioventricular bundle, and vary in density and disposition around the valvular circumference. Extending from the right fibrous trigone component of the central fibrous body are a pair of curved, tapered, subendocardial tendons, or 'prongs' (fila coronaria) that partly encircle the circumference. The latter is completed by more tenuous, deformable fibroblastic sulcal areolar tissue. Although the extent of fibrous tissue varies with sex and age, the tissue within the atrioventricular junction around the tricuspid orifice is always less robust than similar elements found at the
attachments of the mitral valve. The topographical 'attachment' of the free valvular
cusps in the tricuspid valve does not wholly correspond to the internal level of
attachment of the fibrous core of the valve to the junctional atrioventricular connective
tissue: the line of attachment of the cusp is best appreciated in the heart when
examined grossly, and this feature is also more readily discerned clinically.

**Tricuspid valve cusps**

It is usually possible to distinguish three cusps in the tricuspid valve, hence the name. They are located anterosuperiorly, septally and inferiorly, corresponding to the
marginal sectors of the atrioventricular orifice so named. Each is a reduplication of
endocardium enclosing a collagenous core, continuous marginally and on its
ventricular aspect with diverging fascicles of chordae tendineae (see below) and
basally confluent with the annular connective tissue. All cusps of the atrioventricular
valves display, passing from the free margin to the inserted margin, rough, clear and
basal zones. The rough zone is relatively thick, opaque and uneven on its ventricular
aspect where most chordae tendineae are attached. The atrial aspect of the rough
zone makes contact with the comparable surface of the adjacent cusps during full
closure of the valve. The clear zone is smooth and translucent, receives few chordae
tendineae and has a thinner fibrous core. The basal zone, extending 2–3 mm from the
circumferential attachment of the cusps, is thicker, contains more connective tissue
and is vascularized and innervated. It contains the insertions of the atrial myocardium.

The anterosuperior cusp is the largest component of the tricuspid valve. It is attached
chiefly to the atrioventricular junction on the posterolateral aspect of the
supraventricular crest, but extends along its septal limb to the membranous septum,
ending at the anteroseptal commissure. One or more notches often indent its free
margin. The attachment of the septal cusp passes from the inferoseptal commissure
on the posterior ventricular wall across the muscular septum and then angles across
the membranous septum to the anteroseptal commissure. The septal cusp defines
one of the borders of the triangle of Koch, thereby aiding location of the
atrioventricular node, which lies at the apex of the triangle, and ensuring that this area
can be avoided when operating on the tricuspid valve (Figs 56.4A,B; 56.5).

The inferior cusp is wholly mural in attachment and guards the diaphragmatic surface
of the atrioventricular junction. Its limits are the inferoseptal and anteroinferior
commissures.

**Chordae tendineae (tendinous cords)**

The chordae tendineae are fibrous collagenous structures supporting the cusps of the
atrioventricular valves. False chordae connect papillary muscles to each other or to
the ventricular wall including the septum, or pass directly between points on the wall
(or septum, or both); they are irregular in numbers and dimensions in the right
ventricle. The true chordae usually arise from small projections on the tips or margins
of the apical one-thirds of papillary muscles, but sometimes arise from the bases of
papillary muscles or directly from the ventricular walls and the septum. They are
attached to various parts of the ventricular aspects or the free margins of the cusps.
They have been classified into first-, second- and third-order chordae according to the
distance of the attachment from the margins of the cusps; this scheme has little
functional or morphological merit.
Fan-shaped chordae have a short stem from which branches radiate to attach to the margins (or the ventricular aspect) of the zones of apposition between cusps and to the ends of adjacent cusps. Rough zone chordae arise from a single stem which usually splits into three components that attach to the free margin, the ventricular aspect of the rough zone and to some intermediate point on the cusp, respectively. Free-edge chordae are single, thread-like and often long, passing from either the apex or the base of a papillary muscle into a marginal attachment, usually near the midpoint of a cusp or one of its scallops. Deep chordae, also long, pass beyond the margins and, branching to various extents, reach the more peripheral rough zone or even the clear zone. Basal chordae are round chordae or flat ribbons, long and slender, or short and muscular. They arise from the smooth or trabeculated ventricular wall and attach to the basal component of a cusp.

**Papillary muscles**

The two major papillary muscles in the right ventricle are located in anterior and posterior positions. A third, smaller muscle has a medial position together with several smaller, and variable, muscles attached to the ventricular septum. The anterior papillary muscle is largest. Its base arises from the right anterolateral ventricular wall below the anteroinferior commissure of the inferior cusp and it also blends with the right end of the septomarginal trabecula. The posterior, or inferior, papillary muscle arises from the myocardium below the inferoseptal commissure and is frequently bifid or trifid. The septal, or medial, papillary muscle is small but typical, and arises from the posterior septal limb of the septomarginal trabecula. All the major papillary muscles supply chordae to adjacent components of the cusps they support. A feature of the right ventricle is that the septal cusp is tethered by individual chordae tendineae directly to the ventricular septum; such septal insertions are never seen in the left ventricle. When closed, the three cusps fit snugly together, the pattern of the zones of apposition confirming the trifoliate arrangement of the tricuspid valve.

**Opening of the tricuspid valve**

Despite its name, the tricuspid valve acts more like a bicuspid valve, because the septal cusp, the smallest of the three cusps, is fixed between the right and left fibrous trigones and the atrial and ventricular septa. The remainder of the tricuspid anulus is muscular. During diastole the right ventricle relaxes, the anulus dilates and the large anterior and posterior cusps move away from the plane of the anulus into the right ventricle. During systole the anulus constricts as the right ventricle contracts, and the two major cusps move like sails to abut a relatively immobile septal cusp and the septum itself (Fig. 56.7).
Pulmonary valve

The pulmonary valve, guarding the outflow from the right ventricle, surmounts the infundibulum and is situated at some distance from the other three cardiac valves (Figs 56.8, 56.9, 56.10). Its general plane faces superiorly to the left and slightly posteriorly. It has three semilunar cusps attached by convex edges partly to the infundibular wall of the right ventricle and partly to the origin of the pulmonary trunk. The line of attachments is curved, rising at the periphery of each cusp near their zones of apposition (the commissures) and reaching the sinutubular ridge of the pulmonary trunk (Fig. 56.11A–C). Removal of the cusps shows that the fibrous semilunar attachments enclose three crescents of infundibular musculature within the
pulmonary sinuses, whereas three roughly triangular segments of arterial wall are incorporated within the ventricular outflow tract beneath the apex of each commissural attachment. There is, thus, no proper circular ‘anulus’ supporting the cusps of the valve, and the fibrous semilunar attachment is an essential requisite for snug closure of the nodules and lunules of the cusps (see below) during ventricular diastole. It is difficult to name the cusps and corresponding sinuses of the pulmonary valve and trunk precisely according to the coordinates of the body, because the valvular orifice is obliquely positioned. The official nomenclature (Terminologia Anatomica 1998) refers to an anterior, a posterior and a septal cusp, based on their position in the fetus. The position changes with development and in the adult there is one anterior semilunar cusp, and right and left semilunar cusps.

Fig. 56.9  The base of the ventricles, after removal of the atria and the pericardium. Coronary arteries and cardiac veins can be seen. Contrast the planes and positions of the aortic and pulmonary valves. Contrast with Fig. 56.10.

(From Sobotta 2006.)
Fig. 56.10  Principal elements of the fibrous skeleton of the heart. For clarity, the view is from the right posterosuperior aspect. Perspective causes the pulmonary anulus to appear smaller than the aortic anulus, whereas in fact the reverse is the case. Consult text for an extended discussion.

(Copyright from The Royal College of Surgeons of England. Reproduced with permission.)
Each cusp is a fold of endocardium, with an intervening, and variably developed, fibrous core. The core is substantial along both the free edge and the semilunar attached border; the latter is particularly thickened at the deepest central part (nadir) of the base of each cusp (thus never forming a simple complete fibrous ring). The free margin of each cusp contains a central localized thickening of collagen, the nodule of the semilunar 'cusp' (nodule of Arantius). Perforations within the cusps close to the free margin and near the commissures are frequently present, but are of no functional
significance. Each semilunar cusp is contained within one of the three sinuses of the pulmonary trunk.

**Opening of the pulmonary valve**

During diastole, the pulmonary valve is closed and all three cusps of the valve are tightly apposed. The pulmonary valve is difficult to visualize at echocardiography and usually only the posterior cusp is visible when the valve is closed; atrial systole may cause a slight posterior movement of the valve cusps. The pulmonary valve opens passively during ventricular systole and then closes rapidly at the end of systole (Fig. 56.7).

**Left atrium**

Although smaller in volume than the right, the left atrium has thicker walls (3 mm on average). Its cavity and walls are formed largely by the proximal parts of the pulmonary veins, which are incorporated into the atrium during development. The only clear derivative of the left part of the embryonic atrium is the auricle, together with the vestibule of the mitral valve. The left atrium is roughly cuboidal and extends behind the right atrium, separated from it by the obliquely positioned septum, thus the right atrium is in front and anterolateral to the right part of the left atrium. The left part is concealed anteriorly by the initial segments of the pulmonary trunk and aorta: part of the transverse pericardial sinus lies between it and these arterial trunks. Anteroinferiorly, and to the left, it adjoins the base of the left ventricle at the orifice of the mitral valve. Its posterior aspect forms most of the anatomical base of the heart and is approximately quadrangular, receiving the terminations of (usually) two pulmonary veins from each lung. It forms the anterior wall of the oblique pericardial sinus (Fig. 56.1). This surface ends at the shallow vertical interatrial groove, which descends to the cardiac crux. The left atrial auricle is constricted at its atrial junction and all the pectinate muscles of the left atrium are contained within it. It is characteristically longer, narrower and more hooked than the right auricle, its margins being more deeply indented. It turns forwards to the left of the pulmonary trunk, overlapping its origin (Fig. 56.8). Interiorly, the four pulmonary veins open into the upper posteroslateral surfaces of the left atrium, two on each side. Their orifices are smooth and oval, the left pair frequently opening via a common channel. Some minimal cardiac veins return blood directly from the myocardium to the cavity of the left atrium. The left atrial aspect of the septum has a characteristically rough appearance, bounded by a crescentic ridge, concave upwards, which marks the site of the foramen ovale.

**Left ventricle**

**General and external features**

The left ventricle is constructed in accordance with its role as a powerful pump that sustains pulsatile flow in the high-pressured systemic arteries. Various described as half-ellipsoid or cone-shaped, it is longer and narrower than the right ventricle, extending from its base in the plane of the atroventricular groove to the cardiac apex. Its long axis descends forwards and to the left. In transverse section, at right angles to the axis, its cavity is oval or nearly circular, with walls about three times thicker (8–12 mm) than those of the right ventricle (Fig. 56.12). It forms part of the sternocostal, left and inferior (diaphragmatic) cardiac surfaces. Except where obscured by the aorta
and pulmonary trunk, the base of the ventricular cone is superficially separated from the left atrium and atrial auricle by part of the atrioventricular groove; the coronary sinus runs in the posterior aspect of the groove to reach the right atrium (Fig. 56.2B,D). The anterior and posterior interventricular grooves indicate the lines of mural attachment of the ventricular septum and the limits of the left and right ventricular territories. The sternocostal surface of the ventricle curves bluntly into its left surface at the obtuse margin.

**Fig. 56.12** Left and right ventricles: cross section perpendicular to axis of the heart; superior aspect. *(From Sobotta 2006.)*

**Internal features**

The left ventricle has an inlet region, guarded by the mitral valve (ostium venosum), an outlet region, guarded by the aortic valve (ostium arteriosum), and an apical trabecular component. The left atrioventricular orifice admits atrial blood during diastole, flow being towards the cardiac apex. After closure of the mitral cusps, and throughout the ejection phase of systole, blood is expelled from the apex through the aortic orifice. In contrast to the orifices within the right ventricle, those of the left ventricle are in close contact, with fibrous continuity between the cusps of the aortic and mitral valves (the subaortic curtain; Fig. 56.13). The inlet and outlet turn sharply round this fibrous curtain (Fig. 56.9).
The anterolateral wall is the concavo-convex ventricular septum, a muscular wall the convexity of which is the posteromedial profile of the right ventricle as seen in section. It thus completes the circular outline of the left ventricle (Fig. 56.12). Towards the aortic orifice, the septum becomes the thin, collagenous interventricular component of the membranous septum, an oval or round area below and confluent with the fibrous triangle separating the right and the non-coronary cusps of the aortic valve.

Between the lower limits of the free margins of the cusps of the mitral valve and the apex of the ventricle, the muscular walls are deeply trabeculated. These trabeculae carneae are finer and more intricate than those of the right ventricle, but similar in structure. Trabeculation is characteristically well developed near the apex, whereas the upper reaches of the septal surface are smooth (Fig. 56.13).

**Hypertrophy of heart muscle**

In hypertrophic cardiomyopathy, there is an increase in the thickening of the myocardial walls, particularly the interventricular septum, which is disproportionately thickened in comparison with the posterior wall. Echocardiography allows accurate assessment of the thickening and of systolic function. Other features in hypertrophic cardiomyopathy are dynamic left ventricular outflow obstruction, systolic anterior motion of the anterior mitral valve cusp, and midsystolic closure of the aortic valve. A degree of diastolic dysfunction is also present in some cases of hypertrophic cardiomyopathy. Serial short-axis magnetic resonance imaging (MRI) allows accurate measurement of wall thickness and is particularly useful in assessing hypertrophy.
confined to the apex. Gradient-echo MRI also allows some functional assessment of the hypertrophy. A number of histological changes are observed, including disarray of the cardiac myocytes with replacement fibrosis, and expansion of the collagen component. Treatment is usually medical, except for refractory cases and those in whom the left ventricular outflow tract obstruction has a gradient of greater than 50 mmHg. Ventricular septal myotomy and myectomy are performed in such cases. More recently, catheter alcohol septal ablation has been introduced as a non-surgical alternative. A number of patients may also require implantation of cardiac defibrillators to prevent sudden cardiac death.

An athlete's heart may also hypertrophy and may require differentiation from hypertrophic cardiomyopathy. However, in athletes there is uniform hypertrophy, the left ventricle cavity is usually less than 55 mm in size, and the thickness decreases with deconditioning. Hypertrophic cardiomyopathy, in contrast, may show unusual patterns of left ventricular hypertrophy, which is often asymmetric with sharp transitions between segments, left atrial enlargement and bizarre electrocardiographic patterns. Furthermore, there is an autosomal dominant inheritance pattern of abnormalities in genes coding for myocardial proteins associated with hypertrophic cardiomyopathy. Individuals with mutations of the β-MHC (major histocompatibility complex) gene usually develop the classical form of hypertrophy, whereas those with cardiac troponin T gene mutations generally have only mild or clinically undetectable hypertrophy. Rare forms of hypertrophy include localized left ventricular apical hypertrophy as a result of cardiac troponin I mutations, and isolated midcavity hypertrophy caused by cardiac actin and MLC (myosin light chain) gene mutations.

Mitral valve

The general comments already made in respect to the tricuspid valve apply equally to the mitral. The valve has an orifice with its supporting anulus, cusps and a variety of chordae tendineae and papillary muscles.

Mitral valvular orifice

The mitral orifice is a well-defined transitional zone between the atrial wall and the bases of the cusps. It is smaller than the tricuspid orifice (mean circumference is 9.0 cm in males, 7.2 cm in females). The approximately circular orifice is almost vertical in diastole and at 45° to the sagittal plane, but with a slight forward tilt. Its ventricular aspect faces anterolaterally to the left and a little inferiorly towards the left ventricular apex. It is almost co-planar with the tricuspid orifice but posterosuperior to it, whereas it is posteroinferior and slightly to the left of the aortic orifice. The mitral, tricuspid and aortic orifices are intimately connected centrally at the central fibrous body. When the cusps of the mitral valve close, they form a single zone of coaptation, sometimes termed the commissure.

The anulus of the valve is not a simple fibrous ring, but is made up of fibrocollagenous elements of varying consistency from which the fibrous core of the cusps take origin. These variations allow major changes in the shape and dimensions of the anulus at different stages of the cardiac cycle and ensure optimal efficiency in valvular action.

The anulus is strongest at the internal aspects of the left and right fibrous trigones. Extending from these structures, the anterior and posterior coronary prongs (which are tapering, fibrous, subendocardial tendons) partly encircle the orifice at the
atrioventricular junction (Figs 56.9, 56.10). Between the tips of the prongs, the atrial and ventricular myocardial masses are separated by a more tenuous sheet of deformable fibroelastic connective tissue. Spanning anteriorly between the trigones, the fibrous core of the central part of the anterior aortic cusp of the mitral valve is a continuation of the fibrous subaortic curtain that descends from the adjacent halves of the left and non-coronary cusps of the aortic valve (Fig. 56.13).

**Mitral valve cusps**

Since the earliest descriptions, the mitral valvular cusps have been described as paired structures. Hence, the name ‘bicuspid valve’ is more explicit, although erroneous (the cusps are not cuspid, or ‘peaked’, in form) and surely less picturesque than the clinical term ‘mitral’. Confusion, controversy and difficulties in quantitation have arisen, however, because small accessory cusps are almost always found between the two major cusps. These problems can be resolved if the mitral valve is described as consisting of a continuous veil attached around the entire circumference of the mitral orifice. Its free edge bears several indentations; two are sufficiently deep and regular to be nominated as the ends of a solitary and oblique zone of apposition, or commissure. It is more usual, however, for these anteromedial and posterolateral extremities to be designated as two independent commissures, each positionally named as indicated. The official names for these cusps, anterior and posterior, although simple, are somewhat misleading because of the obliquity of the valve.

When the valve is laid open, the anterior cusp (aortic, septal, ‘greater’ or anteromedial) is seen to guard one-third of the circumference of the orifice and to be semicircular or triangular, with few or no marginal indentations. Its fibrous core (lamina fibrosa) is continuous, on the outflow aspect, beyond the margins of the fibrous subaortic curtain, with the right and left fibrous trigones (Figs 56.5, 56.9, 56.11C). Between these, it is continuous with the fibrous curtain itself and, beyond the trigones, with the roots of the anular fibrous prongs (Fig. 56.10). The cusp has a deep crescentic rough zone, which receives various chordae tendineae. The ridge limiting the outer margin of the rough zone indicates the maximal extent of surface contact with the mural cusp in full closure. A clear zone is seen between the rough zone and the valvular anulus, which is devoid of attachments of chordae, although its fibrous core carries extensions from chordae attached in the rough zone. The anterior cusp has no basal zone, continuing instead into the valvular curtain. Hinging on its anular attachment, and continuous with the subaortic curtain, it is critically placed between the inlet and the outlet of the ventricle. During passive ventricular filling and atrial systole, its smooth atrial surface is important in directing a smooth flow of blood towards the body and apex of the ventricle. After the onset of ventricular systole and closure of the mitral valve, the ventricular aspect of its clear zone merges into the smooth surface of the subaortic curtain which, with the remaining fibrous walls of the subvalvular aortic vestibule, forms the smooth boundaries of the ventricular outlet.

The posterior cusp (mural, ventricular, ‘smaller’ or posterolateral) usually has two or more minor indentations. Lack of definition of major intervalvular commissures has previously led to disagreement and confusion concerning the territorial extent of this cusp and the possible existence of accessory ‘scallops’. Examination of the valve in the closed position, however, shows that the posterior cusp can conveniently be regarded as all the valvular tissue posterior to the anterolateral and posteromedial ends of the major zone of apposition with the aortic cusp. Thus defined, it has a wider
attachment to the anulus than does the anterior cusp, guarding two-thirds of the circumferential attachments. Further indentations usually divide the mural cusp into a relatively large middle scallop and smaller anterolateral and posteromedial commissural scallops. Each scallop has a crescentic, opaque rough zone, receiving on its ventricular aspect the attachments of the chordae that define the area of valvular apposition in full closure. From the rough zone to within 2–3 mm of its anular attachment, there is a membranous clear zone devoid of chordae. The basal 2–3 mm is thick and vascular, and receives basal chordae. The ratio of rough to clear zone in the anterior cusp is 0.6; in the middle scallop of the posterior cusp it is 1.4. Much more of the mural cusp is in apposition with the aortic cusp during closure of the mitral valve.

**Mitral chordae tendineae (tendinous cords)**

The chordae tendineae resemble those supporting the tricuspid valve. False chordae (trabeculae carneae; Fig. 56.13) are also irregularly distributed as in the right ventricle. They occur in about 50% of all human left ventricles, and often cross the subaortic outflow. Many contain extensions from the ventricular conducting tissues. These left ventricular bands can often be identified by cross-sectional echocardiography. Their role, if any, has still to be determined. True chordae of the mitral valve may be divided into intercusp (or commissural) chordae, rough zone chordae, including the special strut chordae, so-called ‘cleft’ chordae and basal chordae. Most true chordae divide into branches from a single stem soon after their origin from the apical one-third of a papillary muscle, or proceed as single chordae that divide into several branches near their attachment. Basal chordae, in contrast, are solitary structures passing from the ventricular wall to the mural cusp.

There is such marked variation between the arrangement of the chordae in individual normal hearts that any detailed classification loses much of its clinical significance. Suffice it to say that, in the majority of hearts, the chordae support the entire free edges of the valvular cusps, together with varying degrees of their ventricular aspects and bases. There is some evidence to suggest that those valves with unsupported areas of the free edge become prone to prolapse in later life.

**Papillary muscles**

The two muscles supporting the cusps of the mitral valve also vary in length and breadth and may be bifid. The anterolateral muscle arises from the sternocostal mural myocardium, the posteromedial from the diaphragmatic region (Fig. 56.12). Chordae tendineae arise mostly from the tip and apical one-third of each muscle, but sometimes take origin near their base. The chordae from each papillary muscle diverge and are attached to corresponding areas of closure on both valvular cusps.

**Opening of the mitral valve**

At the onset of diastole, opening is passive but rapid, the cusps parting and projecting into the ventricle as left atrial pressure exceeds left ventricular diastolic pressure. Passive ventricular filling proceeds as atrial blood pours to the apex, directed by the pendant aortic cusp of the valve. The cusps begin to float passively together, hinging on their anular attachments, partially occluding the ventricular inlet. Atrial systole now occurs, jetting blood apically and causing re-opening of the cusps. As maximal filling is achieved, the cusps again float rapidly together. Closure is followed by ventricular
systole, which starts in the papillary muscles and continues rapidly as a general contraction of the walls and septum. Coordinated contraction of the papillary muscles increases the tension in the chordae and promotes joining of the corresponding points on opposing cusps, preventing their eversion. With general mural and septal excitation and contraction, left ventricular pressure increases rapidly (Fig. 56.7). The cusps ‘balloon’ towards the atrial cavity and the atrial aspects of the rough zones come into maximal contact. Precise papillary contraction, and increasing tension in the chordae, continue to prevent valvular eversion and maintain valvular competence.

The orifices and the cusps of both atrioventricular valves undergo considerable changes in position, form and area during a cardiac cycle. Both valves move anteriorly and to the left during systole, and reverse their motion in diastole. The mitral valve reduces its orificial (anular) area by as much as 40% in systole. Its shape also changes from circular to crescentic at the height of systole, the anular attachment of its aortic cusp being the concavity of the crescent. The attachment of its mural cusp, although remaining convex, contracts towards the anterior wall of the heart.

**Aortic valve**

The smooth left ventricular outflow tract, or aortic vestibule, ends at the cusps of the aortic valve. Although stronger in construction, the aortic valve resembles the pulmonary (Figs 56.9, 56.11, 56.13) in possessing three semilunar cusps, supported within the three aortic sinuses of Valsalva. Although the aortic valve, like the pulmonary valve, is often described as possessing an anulus in continuity with the fibrous skeleton, there is no complete collagenous ring supporting the attachments of the cusps. As with the pulmonary valve, the anatomy of the aortic valve is dominated by the fibrous semilunar attachment of the cusps (Fig. 56.11C).

**Aortic valve cusps**

The cusps are attached in part to the aortic wall and in part to the supporting ventricular structures. The situation is more complicated than in the pulmonary valve, because parts of the cusps also take origin from the fibrous subaortic curtain, and are continuous with the aortic cusp of the mitral valve (Fig. 56.13). This area of continuity is thickened at its two ends to form the right and left fibrous trigones (Fig. 56.9). However, as with the pulmonary valve, the semilunar attachments incorporate segments of ventricular tissue within the base of each aortic sinus. These sinuses and cusps are conveniently named as right, left and non-coronary, according to the origins of the coronary arteries (Fig. 56.11C). The semilunar attachments also incorporate three triangular areas (trigones) of aortic wall within the apex of the left ventricular outflow tract. As these triangular areas are part of the wall of the aorta rather than of the left ventricle, and are interposed between the bulbous aortic sinuses, they separate the cavity of the left ventricle from the pericardial space. Removal of the trigones in an otherwise intact heart is instructive in demonstrating the relationships of the aortic valve, which can justly be considered as the keystone of the heart. The base of the triangle between the non-coronary and the left coronary cusps is continuous inferiorly with the fibrous aortic-mitral curtain. The apex of this triangle ‘points’ into the transverse pericardial space. The triangle between right and non-coronary cusps has, as its base, the membranous components of the interventricular septum and thus ‘faces’ the right ventricle, whereas its apex ‘points' towards the transverse pericardial space behind the origin of the right coronary artery. The third
triangle, between the two coronary cusps, has its base on the muscular ventricular septum. Its apex 'points' to the plane of space found between the aortic wall and the free-standing sleeve of right ventricular infundibular musculature that supports the cusps of the pulmonary valve. Although the basal attachments of each cusp are thickened and collagenous at their ventricular origins, there is no continuous collagenous skeleton supporting, in circular fashion, all the attachments of the cusps of the aortic valve. Valvular function depends primarily upon the semilunar attachments of the cusps.

The cusps themselves are folds of endocardium with a central fibrous core. With the valve half open, each equals slightly more than a quarter of a sphere, an approximate hemisphere being completed by the corresponding sinus. Each cusp has a thick basal border, deeply concave on its aortic aspect, and a horizontal free margin. The latter is only slightly thickened, except at its midpoint, where there is an aggregation of fibrous tissue, the valvular nodule of the semilunar cusp. The fibrous core that flanks each nodule is tenuous, forming the lunules of translucent and occasionally fenestrated valvular tissue; fenestrations are of no functional significance. The aortic surface of each cusp is rougher than its ventricular aspect.

Currently, three sets of names are used to describe the aortic cusps. Posterior, right and left refer to presumed fetal positions before full cardiac rotation has occurred (Ch. 59). Corresponding terms based on the approximate positions in maturity are anterior, left posterior and right posterior. However, as already indicated, widespread clinical terminology links both cusps and sinuses to the origins of the coronary arteries. Thus, the anterior is termed the right coronary cusp, the left posterior is the left coronary, and the right posterior is the noncoronary; these clinical terms are preferable, in the normal heart, because they are simple and unambiguous.

Aortic sinuses (of Valsalva)

The aortic sinuses are more prominent than those in the pulmonary trunk. The upper limit of each sinus reaches considerably beyond the level of the free border of the cusp and forms a well-defined complete circumferential sinotubular ridge when viewed from the aortic aspect (Fig. 56.11C). Coronary arteries usually open near this ridge within the upper part of the sinus, but are markedly variable in their origin. The walls of the sinuses are largely collagenous near the attachment of the cusps, but the amount of lamellated elastic tissue increases with distance from the zone of attachment. Strands of myocardium may enter this fibroelastic wall. At the mid level of each sinus, its wall is about half the thickness of the supravalvular aortic wall and less than one-quarter of the thickness of the sinutubular ridge. At this level, the mean luminal diameter of the beginning of the aortic root is almost double that of the ascending aorta. These details are functionally significant in the mechanism of valvular motion.

Opening of the aortic valve

During diastole, the closed aortic valve supports an aortic column of blood at high but slowly diminishing pressure (Fig. 56.7). Each sinus and its cusp form a hemispherical chamber. The three nodules are apposed and the margins and lunular parts of adjacent cusps are tightly apposed on their ventricular aspects. From the aortic aspect, the closed valve is triradiate, three pairs of closely compressed lunules radiating from their nodules to their peripheral commissural attachments at the
sinutubular junction (Fig. 56.9). As ventricular systolic pressure increases, it exceeds aortic pressure and the valve is passively opened. The fibrous wall of the sinuses nearest the aortic vestibule is almost inextensible but, in the upper parts of sinuses, the wall is fibroelastic. Under left ventricular ejection pressure, the radius here increases 16% in systole. Hence the commissures move apart, making the orifice triangular when fully open. The free margins of the cusps then become almost straight lines between peripheral attachments. However, they do not flatten against the sinus walls, even at maximal systolic pressure, which is probably an important factor in subsequent closure. During ejection, most blood enters the ascending aorta, but some enters the sinuses, forming vortices that help to maintain the triangular ‘mid position’ of the cusp during ventricular systole and probably initiate their approximation with the end of systole. Tight and full closure ensues, with the rapid decrease in ventricular pressure in diastole. Commissures narrow, nodules aggregate and the valve reassumes its triradiate form. Experiments indicate that 4% of ejected blood regurgitates through a valve with normal sinuses, whereas 23% regurgitates through a valve without them. The normal structure of the aortic sinuses also promotes non-turbulent flow into the coronary arteries.

**Echocardiography**

The gross anatomy of the heart can be evaluated by two-dimensional echocardiography in the para-sternal, apical, suprasternal and subcostal positions (Fig. 56.14). The standardized planes used are long axis, short axis and four-chamber. Echocardiography allows a detailed assessment of the functional anatomy of the heart. The long-axis view is obtained by placing the ultrasound transducer in the left apicosternal position and provides detailed images of the left ventricle, aorta, left atrium, and mitral and aortic valves (Fig. 56.14C). Angling the beam towards the right also allows assessment of the right atrium, right ventricle and tricuspid valves. Rotating the transducer by 90° in the clockwise direction produces the short-axis view, which allows assessment of the left ventricle, papillary muscles, chordae tendineae and mitral and aortic valves (Fig. 56.14B). The four-chamber view demonstrates the ventricles, atria, and mitral and tricuspid valves (Fig. 56.14A). Rotation of the transducer allows two-chamber views of the heart and more detailed assessment of the aorta and aortic valves. Cardiac magnetic resonance and computer tomography provide similar information on cardiac structure and function (Fig. 56.14D–F), together with complementary information on great vessels and other extracardiac intrathoracic structures.
Fig. 56.14  Cardiac anatomy shown by transthoracic echocardiography and computed tomography. 

**A**, Four-chamber view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. **B**, Short-axis view at aortic valve level. Note three aortic cusps R, right; L, left; and NC, non-coronary; and central position of the aorta: LA, left atrium; PV, pulmonary valve; RA, right atrium; RV, right ventricle; TV, tricuspid valve. **C**, Parasternal long-axis view; AV, aortic valve; LA, left atrium; LV, left ventricle; MV, mitral valve. **D**, E, and F, Corresponding images by computed tomography. Note different orientation compared with transthoracic echocardiography (looked at from below, foot-to-head). R, right; L, left; A, anterior; P, posterior; H, head; F, foot.

CONNECTIVE TISSUE AND FIBROUS SKELETON OF THE HEART

From epicardium to endocardium, and from the orifices of the great veins to the roots of the arterial trunks, the intercellular spaces between contractile and conduction elements are everywhere permeated by connective tissue. The amount varies greatly in arrangement and texture in different locations.

A fine layer of areolar tissue is found beneath the mesothelium of the serosal visceral epicardium over much of the heart. This accumulates subepicardial fat which becomes concentrated along the acute margin, the atrioventricular and interventricular grooves and their side channels. The coronary vessels and their main branches are embedded in this fat; the amount increases with age. The endocardium also lies on a fine areolar tissue rich in elastic fibres. Fibrocellular components of these subepicardial and subendocardial layers blend on their mural aspects with the endomysial and perimysial connective tissue on the myocardium. Each cardiac myocyte is invested by a delicate endomysium composed of fine reticular fibres, collagen and elastin fibres embedded in ground substance. This matrix is lacking only at desmosomal and gap junctional contacts of intercalated discs. Similar arrangements apply to myocytes of the ventricular conduction tissues and their extensive contacts with the working myocardium. The connective tissue matrix itself is interconnected laterally to form bundles, strands or sheets of macroscopic proportions showing a complex geometric pattern. The larger myocardial bundles are surrounded by, and attached to, stronger perimysial condensations. The overall pattern is described in terms of struts and weaves.

The myocardial matrix, despite its importance, cannot be dissected grossly. Running at the ventricular base, and intimately related to atrioventricular valves and the aortic orifice, is a complex framework of dense collagen with membranous, tendinous and fibroareolar extensions. The whole is sufficiently distinct to be termed the fibrous skeleton of the heart.

Although it is often stated that all four valves are contained within this skeleton, this is not the case. The cusps of the pulmonary valve are supported on a free-standing sleeve of right ventricular infundibulum which can easily be removed from the heart without disturbing either the fibrous skeleton or the left ventricle. The fibrous skeleton is strongest at the junction of the aortic, mitral and tricuspid valves, the so-called central fibrous body (see below) (Figs 56.9, 56.10). Two pairs of curved, tapering, collagenous prongs, fila coronaria, extend from the central fibrous body. They are stronger on the left, passing partially around the mitral and tricuspid orifices, which are almost co-planar and incline to face the cardiac apex. The aortic valve, in contrast, faces up, right and slightly forwards. It is anterosuperior and to the right of the mitral orifice. Two of the cusps of the aortic valve are in fibrous continuity with the aortic cusp of the mitral valve: this aortic-mitral or
The subaortic curtain is also an integral part of the fibrous skeleton (Figs 56.9, 56.11C). The two ends of the curtain are strengthened as the right and left fibrous trigones, which are the strongest part of the skeleton. The right trigone, together with the membranous septum, constitutes the central fibrous body, which is penetrated by the bundle of His, or atrioventricular bundle, i.e. by the mechanism for atrioventricular conduction. The membranous septum is crossed on its right aspect by the attachment of the tricuspid valve, which divides the septum into atrioventricular and interventricular components.

The fibrous skeleton has two functions. It ensures electrophysiological discontinuity between the atrial and ventricular myocardial masses (except at the site of penetration of the conduction tissue), and it also functions as a stable but deformable base for the attachments of the fibrous cores of the atrioventricular valves.

The aortic root is central within the fibrous skeleton and is often described in terms of an ‘anulus’ integrated within the fibrous skeleton. However, as with the pulmonary valve, the structure of the aortic root corresponds to the triple fibrous semilunar attachments of its cusps. Within this complex circumferential zone there are three crucially important triangular areas that separate, on the ventricular aspect, the aortic bulbous sinuses which house the valvular cusps. As a whole, these three triangles can be conceptualized in terms of a three-pointed coronet and are known as the subaortic spans. Their triangular apices correspond to the tips of the valvular commissures. Their walls, which are significantly thinner than those of the sinuses, variously consist of collagen or admixed muscle strands and fibroelastic tissue. They form the subvalvular extensions of the aortic vestibule. The interval between the non-coronary and left coronary sinuses is filled with the deformable subaortic curtain. The span between the non-coronary and right coronary sinuses is continuous with the anterior surface of the membranous septum. The third subaortic span, between the two coronary aortic sinuses, is filled with fibroelastic tissue, which separates the extension of the subaortic root from the wall of the free-standing subpulmonary infundibulum. Previously, this was thought to be the location of the tendon of the infundibulum (conus ligament). Similar fibrous triangles are found separating the sinuses of the pulmonary trunk, but these are significantly less robust.

The mitral and tricuspid rings (anuli) are not simple and rigid collagenous structures but dynamic, deformable lines of valvular attachment that vary greatly at different peripheral points and change considerably with each phase of the cardiac cycle and with increasing age. The tricuspid attachments are even less robust than those of the mitral valve. At several sites only fibroareolar tissue separates the atrial and ventricular muscular masses.
CONGENITAL CARDIAC MALFORMATIONS

Congenital malformations of the heart are common, amounting to about one-quarter of all developmental abnormalities. Their incidence is estimated at eight per 1000 live births, but they are found in up to 2% of stillbirths. Only a small proportion of the anomalies are directly attributable to genetic or environmental factors; the majority are the result of multifactorial events.

Abnormalities of cardiac position

The most severe abnormality of position is an extrathoracic heart, so-called ectopia cordis. The heart usually projects to the surface through the lower thoracic and upper abdominal wall, remaining covered, in most instances, by the fibrous pericardium. There is usually additional herniation of the abdominal contents. Another abnormality of cardiac position is a mirror-image i.e. reversal in shape and position of the heart: the heart is predominantly positioned in the right hemithorax (dextroposition) with its apex directed to the right instead of the left (dextrocardia). This arrangement may be part of 'situs inversus', where the heart, great vessels and abdominal organs occupy mirror-image positions. Dextrocardia may be associated with Kartagener's syndrome (a subgroup of ciliary dyskinesias). More usually, an abnormal location of the heart occurs in cases of isomerism, in which both sides of the thorax, including the main bronchi and the atrial appendages, retain features of either morphological rightness or leftness. Isomerism is also commonly associated with anomalous arrangement of the abdominal organs, right isomerism is associated with 'absence' of the spleen (so called asplenia) and left isomerism with multiple spleens (polysplenia). The intracardiac anatomy in cases of isomerism is almost universally abnormal, and there is a range of heart defects (the defects are usually more simple in left atrial isomerism, and more complex in right atrial isomerism). These intrathoracic abnormal arrangements, with or without abdominal abnormalities, may first manifest themselves following 'routine' chest radiography. Reversal of normal anatomy has obvious clinical implications, a typical example being a patient with mirror-image arrangements and appendicitis, who presents with an acute left lower quadrant pain.

Most congenital heart abnormalities can be detected during antenatal ultrasound screening. Neonates with severe congenital heart disease may present with tachypnoea, difficulty in feeding, cyanosis and/or cardiovascular collapse. There may be audible murmurs on auscultation. The vast majority of abnormalities may be detected by postnatal echocardiography; in a very few cases, cardiac catheterization and direct measurements of pressure, oxygen saturations and angiography may be required.

Acyanotic cardiac defects

Acyanotic heart defects are the result of either left to right cardiac shunting through heart defects (intra- or extra-cardiac), or of obstruction. Left to right shunting leads to an increased workload and stress on the heart and the lungs as a consequence of increased pulmonary blood flow and, in turn, increased pulmonary venous return. Depending on the location of the shunt and the magnitude of left to right shunting, patients are at risk of developing pulmonary arterial hypertension, unless timely heart surgery is undertaken. Examples of defects leading to left to right shunting are simple septal defects such as atrial or ventricular septal defects or patent ductus arteriosus,
or more complex cardiac defects, including atrioventricular septal defects, and/or a combination of any of these defects with abnormal atrioventricular or ventriculoarterial connections (e.g. a double outlet right ventricle, where more than 50% of both the aorta and the pulmonary artery originate from the right ventricle) (Ch. 59). Obstructive lesions may involve the atrioventricular or semilunar valves (mitral, aortic or pulmonary valve stenosis), or narrow vessels (e.g. coarctation of the aorta or interrupted aortic arch). Depending on the level and severity of the obstruction, patients may have a range of clinical presentations from an asymptomatic heart murmur (common) to cardiovascular collapse (uncommon). Treatment in all cases is directed towards normalizing heart workload, systemic and pulmonary blood flow, and cardiac output, and may be surgical and/or catheter-based.

**Cyanotic cardiac defects**

Cyanotic cardiac defects may be attributable to a right to left intra- or extra- cardiac shunt or to a severe reduction in pulmonary blood flow. They may be caused by simple lesions such as severe pulmonary stenosis with an atrial septal defect and right to left shunting; moderate lesions including Fallot's tetralogy, in which there is a ventricular septal defect, right ventricular outflow obstruction, right ventricular hypertrophy and an over-riding aorta; or more complex lesions including transposition of the great arteries (Fig. 56.15A,B) and tricuspid and pulmonary atresia (often in the setting of hypoplastic right ventricle and ‘single’ ventricular physiology). Neonates with severe cyanotic congenital heart defects may be dependent on the patency of the ductus arteriosus: early diagnosis, treatment with intravenous prostaglandin infusion and timely transfer to a tertiary centre for more definitive therapy, is key to survival and good long-term outcomes.
In recent years, major advances in the diagnosis and management of infants with congenital cardiac malformations have resulted in an increased number of adolescents and adults with palliated or repaired, but not cured, congenital heart disease. This is an area that poses multiple challenges to both cardiovascular and other medical disciplines.
CONDUCTION TISSUE

The cells of cardiac muscle differ from those of skeletal muscle in having the inherent ability to contract and relax spontaneously. This myogenic rhythm is shown by small pieces of cardiac tissue, and even isolated myocytes. The underlying mechanism appears to be based on a further specialization of the sarcolemma that permits a slow inward leakage of sodium ions. Ventricular cells contract and relax at a lower frequency than atrial cells, but in the intact heart both are synchronized to a more rapid rhythm, generated by pacemaker tissue and conveyed to them by a system of fibres specialized for conduction. The anatomical arrangement of these tissues is described in the context of the heart. Here, consideration is restricted to the cells that make up the impulse-generating and conduction system. All are modified cardiac cells. Three types may be distinguished morphologically from normal working cardiac cells: P (=pale-staining = primitive = pacemaker) cells; transitional cells; and Purkinje fibres.

Although these terms will be used in the following account, it is important to recognize that there is a continuum of morphology between P cells, transitional cells, Purkinje fibres and working cardiac muscle cells.

Overview of the conduction system

Of all the cells in the heart, those of the sinu-atrial node generate the most rapid rhythm, and therefore function as the pacemaker of the heart. The impulse, believed to be generated in the P cells, is transmitted over preferentially conducting pathways to right and left atria and to the atrioventricular node. At the atrioventricular node, the impulse is delayed by 40 ms. This delay allows the atria to eject their contents fully before contraction of the ventricles begins. It also places an upper limit on the frequency of signals that can be transmitted to the ventricles. Slender transitional cells, closer in morphology to normal cardiac cells, extend from the node into the stem and principal branches of the atrioventricular bundle (of His). Here, they become continuous with cells of more distinctive appearance, the Purkinje fibres. Conduction of the impulse is rapid in the bundle and its branches (2–3 metres per second, as opposed to 0.6 metres per second in normal myocardium). The cardiac impulse therefore arrives at the apex of the heart before spreading through the ventricular walls, producing a properly coordinated ventricular ejection.

The human heart beats ceaselessly at 70 cycles every minute for many decades, maintaining perfusion of pulmonary and systemic tissues. The rate and stroke volume fluctuate in response to prevailing physiological demands. Figure 56.7 summarizes the principal events in a cardiac cycle, including: the electrical events recorded in the electrocardiogram; the mechanical sequences of diastole, atrial systole, isovolumetric contraction, ejection and isovolumetric relaxation in ventricular systole; the acoustic phenomena recorded in the phonocardiogram; the pressure profiles of right and left hearts and arterial trunks; the sequences of valvular events. Cardiac efficiency depends on precise timing of the operation in interdependent structures. Passive diastolic filling of the atria and ventricles is followed by atrial systole, stimulated by discharge from the sinu-atrial node, which completes ventricular filling. Excitation and contraction of the atria must be synchronous and finish before ventricular contraction. This is effected by a delay in the conduction of excitation from atria to ventricles. Thereafter, ventricular contraction proceeds in a precise manner. A specialized
ventricular conduction system ensures that closure of atrioventricular valves is followed rapidly by a wave of excitation and contraction, which spreads from the ventricular apices towards the outflow tracts and orifices, rapidly accelerating the blood during ejection.

Cardiac contraction originates unequivocally in specialized myocytes, but neural influences are important in adapting the intrinsic cardiac rhythm to functional demands from the entire body. All cardiac myocytes are excitable, and display autonomous rhythmic depolarization and repolarization of the cell membrane, conduction of waves of excitation via gap junctions to adjacent myocytes, and excitation-contraction coupling to their actomyosin complexes. These properties are developed to different degrees in different sites and in different types of myocyte (see Ch. 6). The rate of depolarization and repolarization is slowest in the ventricular myocardium, intermediate in the atrial muscle and fastest in the myocytes of the sinoatrial node. These last over-ride those generating slower rhythms and, in the normal heart, are the locus for the rhythmic initiation of cardiac cycles. Conversely, conduction velocity is slow in nodal myocytes, intermediate in general ‘working’ cardiac myocytes and fastest in the myocytes of the ventricular conduction system.

The nodes and networks of the so-called specialized myocardial cells constitute the cardiac conduction system (Figs 56.4A, 56.16A,B and 56.17). The components of this system are the sinu-atrial and atrioventricular nodes, the atrioventricular bundle with its left and right bundle branches and the subendocardial plexus of ventricular conduction cells (Purkinje fibres). Within the system, the main pacemaker rhythm of the heart is generated (sinus), is influenced by nerves (sinus and its innervation) and is transmitted specifically from atria to ventricles (atrioventricular node and bundle) and, within the ventricles, to all their musculature. The spread of excitation is very rapid, but not instantaneous. Different parts of the ventricles are excited at slightly different times, with important functional consequences. Failure of the conduction system will not block cardiac contraction, but the system will become poorly coordinated or uncoordinated. The rhythm will be slower because it originates from a spontaneous (myogenic) activity in the working cardiac myocytes or in a subsidiary pacemaker in a more distal part of the diseased or disrupted conduction system.
Fig. 56.16 The conduction tissue of the heart: A, right aspect; B, left aspect. The elements of the conduction system are shown in purple. Note the conduction tissue accompanying fine trabeculae carneae and false chordae. In reality, the radiation of the left bundle branch is directly related to the cusps of the aortic valve.
Fig. 56.17  The basic structure of the conduction system, and its relation to the electrocardiogram. Note foramen ovale allowing for communication between the right atrium (RA) and the left atrium (LA). SVC, superior vena cava.  (Redrawn by courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)

There are no specialized internodal and interatrial conduction pathways. The excitation emanating from the sinoatrial node spreads to the atrial musculature and to the atrioventricular node through ordinary atrial working myocardium. The geometric arrangement of fibres along well-organized atrial muscle bundles, e.g. the terminal crest and the rims of the fossa ovale, ensure that conduction is marginally more rapid than elsewhere within the atrium.

**Sinoatrial node**

The sinoatrial node is an elliptical structure, 10–20 mm long. It is located at the junction between parts of the right atrium derived from the embryonic venous sinus and the atrium proper (Figs 56.4A, 56.17). The node is often covered by a plaque of subepicardial fat, making it visible in some instances to the naked eye. It extends between 1 and 2 cm on the right from the crest of the right auricle and runs posteroinferiorly into the upper part of the terminal groove. In a small proportion of
individuals, about 1 in 10, it extends in horseshoe fashion across the crest of the auricle. Nodal tissue does not occupy the full thickness of the right atrial wall from epicardium to endocardium in humans, but rather sits as a wedge of specialized tissue subepicardially within the terminal groove. Its location is marked consistently by a large central artery, which is a branch of either the left circumflex or posterior descending branch of the right coronary artery. Nodal cells are grouped circumferentially around this artery and interwoven into its dense collagenous adventitia. These cells are now considered the 'pacemakers', although the functional implications of this relationship are not fully understood. Many nerve fibres are present, although none appears to terminate on cells. There are no autonomic ganglion cells within the node, although many border it anteriorly and posteriorly. P cells are most abundant in the central region. They are small, empty-looking cells, 5–10 µm in greatest diameter, with a large central nucleus. Their pale appearance is attributable to the sparsity of organelles: myofibrils are few and irregularly arranged, and there is no proper sarcotubular system and little glycogen. P cells are less abundant in the periphery of the node, where they mix with slender fusiform transitional cells which are part of a heterogeneous group that is intermediate in appearance between P cells and normal working cardiac cells, and which link P cells to other cells.

**Atrioventricular node**

The atrioventricular node is an atrial structure that lies at the root of an extensive tree of conduction tissue reaching the apex of the ventricles, the papillary muscles and other regions of the ventricles (Fig. 56.17). The node, with its transitional zones, is located within the atrial component of the muscular atrioventricular septum. Its anatomical landmarks are the boundaries of the triangle of Koch (the attachment of the septal cusp of the tricuspid valve inferiorly, the ostium of the coronary sinus basally, and the tendon of Todaro superiorly) (Fig. 56.4A,B). The compact node is a half oval set against the central fibrous body towards the apex of this triangle. Its atrial aspect is convex, and is overlain by atrial myocardium. Its left margin is concave and abuts on the superior aspect of the central fibrous body. Its basal end projects into the atrial muscle and its anteroinferior end enters the central fibrous body to become the penetrating atrioventricular bundle. The node is pervaded by an irregular collagenous reticulum enmeshing the myocytes, but this is less dense than in the sinu-atrial node. Its arterial supply is from a characteristic vessel that originates from the dominant coronary artery at the crux of the heart. The node has a well-formed compact zone made up of interlocking nodal cells, which frequently show stratification. The transitional cell zones are found superficially and posteriorly. The larger component of atrioventricular delay is probably produced in these transitional zones of the node.

Internodal conduction pathways converge on the atrioventricular node. This is similar in general appearance to the sinoatrial node, although the collagenous component is less dense. The majority of cells are of the transitional type, but P cells resembling those of the sinuatrial node are found in a more fibrous central region. Autonomic ganglia are present between the node and the coronary sinus. In both sinoatrial and atrioventricular nodes, the intercellular contacts between P cells, and between P cells and transitional cells, are much less specialized than the intercalated discs between normal cardiac cells. A sparsity of gap junctions is consistent with the absence from these areas of connexin-43, which is a major protein component of mammalian gap junctions. This probably accounts for the observed difficulty in exciting these cells from
adjacent cells. The atrioventricular delay may owe much to this relative inexcitability of the P cells, which appears to disturb the spread of potential in a manner that delays propagation. The narrow diameter of the transitional cells may contribute to the conduction delay.

**Atrioventricular bundle**

The atrioventricular bundle is the direct continuation of the atrioventricular node, becoming oval, quadrangular or triangular in transverse sectional profile as it enters the central fibrous body (Fig. 56.4A). Traversing the fibrous body, it branches on the crest of the muscular interventricular septum, the branching tract being sandwiched between the muscular and the membranous components of the septum. The right branch of the bundle (crus dextrum) is a narrow, discrete round group of fascicles that courses at first within the myocardium and then subendocardially towards the apex of the ventricle, entering the septomarginal trabecula to reach the anterior papillary muscle. It gives few branches to the ventricular walls in its septal course. At the origin of the anterior papillary muscle, it divides profusely into fine subendocardial fascicles that diverge and, first, embrace the papillary muscle, and then recurve sub-endocardially to be distributed to the remaining ventricular walls. The left branch (crus sinistrum) arises as numerous fine intermingling fascicles that leave the left margin of the branching bundle through much of its course along the crest of the muscular ventricular septum (Fig. 56.16A,B). These fascicles form a flattened sheet down the smooth left ventricular septal surface. The sheet diverges apically and subendocardially across the left aspect of the ventricular septum, separating into anterior, septal and posterior divisions. Fine branches leave the sheets, forming subendocardial networks, which first surround the papillary muscles and then curve back subendocardially to be distributed to all parts of the ventricle.

The principal branches of the bundle are insulated from the surrounding myocardium by sheaths of connective tissue. Functional contacts between ventricular conduction and working myocytes become numerous only in the subendocardial terminal ramifications. Hence, papillary muscles contract first, followed by a wave of excitation and ensuing contraction that travels from the apex of the ventricle to the arterial outflow tract. Because the Purkinje network is subendocardial, muscular excitation proceeds from the endocardial to the epicardial aspect. In the developing heart, it can be shown that the bundle responsible for atrioventricular conduction is a much more extensive structure. Immunohistochemical analysis has revealed that the precursor of the system is a ring of cells that surrounds the inlet and outlet components of the developing ventricular loop (Ch. 59). This ring becomes modified after septation of the ventricles, so that it encircles the right atrioventricular orifice and the aortic outlet from the left ventricle. With subsequent growth, only the septal components of this 'figure of eight' persist as the atrioventricular conduction tract. However, remnants of the aortic ring can persist as a 'dead-end tract'.

The Wolff–Parkinson–White syndrome is caused by abnormal small strands of otherwise unremarkable ventricular myocardium, which connect the atrial and ventricular myocardial masses at some point around the atrioventricular junctions. Histologically, they are strands of working myocardium running through the fibroareolar tissue of the atrioventricular groove.

**Cardiac pacing**
Temporary pacing wires are usually inserted by cannulation of either the internal jugular vein or the subclavian vein. The subclavian vein approach carries a slightly greater risk of a pneumothorax because of the proximity of the pleural cavity. Other potential risks are brachial plexus injury if the entry site is too posterior, and thoracic duct injury if the left subclavian vein is cannulated. With permanent pacemakers, the most common site at which to locate the device is in a subcutaneous pocket on the anterior chest wall. Access to the heart and the endocardium of the right ventricle and right atrium is gained via the cephalic vein as it lies in the deltopectoral groove.

**Cardiac conduction studies**

Intracardiac electrocardiography and electrophysiology are used to assess cardiac conduction and rhythm abnormalities. A catheter is inserted via the femoral, subclavian or internal jugular veins using a guidewire technique. Fluoroscopy, echocardiography, and more recently cardiac magnetic resonance, are used to guide accurate placement of the catheters in the appropriate position. The sites of study are high right atrium (for assessing the atrioventricular bundle and right bundle branch) and the coronary sinus (for evaluating atrioventricular junctional arrhythmias and accessory pathways). The multipolar electrodes provide detailed electroanatomical mapping of the sequence of excitation from the atria, atrioventricular junction and ventricles. The origin of supraventricular arrhythmias, ventricular tachycardias, accessory conduction pathways and re-entrant pathways can be identified and used to guide radiofrequency ablation.

**Congenital conduction abnormalities**

The majority of congenital conduction abnormalities used to have an anatomical basis for their origin, being the product of either accessory pathways or abnormal morphogenesis within the conduction tissue at any point from the atrioventricular node through the atrioventricular bundle. However today, conduction abnormalities are increasingly likely to relate to either long-standing haemodynamic problems and/or the effects of previous surgery for patients with congenital heart defects. This reflects the fact that although surgery for most of these defects has been available for the past four decades, surgery itself has not been curative and patients more often than not develop conduction abnormalities (and arrhythmia) secondary to haemodynamic problems (chamber dilation and/or hypertrophy), due to surgical scars. Very occasionally, conduction abnormalities are caused by tumours such as multifocal Purkinje cell tumours, or benign congenital polycystic tumours of the atrioventricular node.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Coronary arterial supply

The right and left coronary arteries arise from the ascending aorta in its anterior and left posterior sinuses (Figs 56.8, 56.9, 56.18A–E). The levels of the coronary ostia are variable. The two arteries, as indicated by their name, form an oblique inverted crown, in which an anastomotic circle in the atrioventricular groove is connected by marginal and interventricular (descending) loops intersecting at the cardiac apex (Fig. 56.18A–E). This is, of course, only an approximation. The degree of anastomosis varies and is usually insignificant. The main arteries and major branches are usually subepicardial, but those in the atrioventricular and interventricular grooves are often deeply sited, and occasionally hidden by overlapping myocardium or embedded in it.

Fig. 56.18 Anterior views of the coronary arterial system, with the principal variations. The right coronary arterial tree is shown in magenta, the left in full red. In both cases posterior distribution is shown in a paler shade. A, The most common
The term 'dominant' is used to refer to the coronary artery giving off the posterior interventricular (descending) branch, which supplies the posterior part of the ventricular septum and often part of the posterolateral wall of the left ventricle. The dominant artery is usually the right (60%). Anastomoses between right and left coronary arteries are abundant during fetal life, but are much reduced by the end of the first year of life. Anastomoses providing collateral circulation may become prominent in conditions of hypoxia and in coronary artery disease. An additional collateral circulation is provided by small branches from mediastinal, pericardial and bronchial vessels.

The calibre of coronary arteries, both main stems and larger branches, based on measurements of arterial casts or angiograms, ranges between 1.5 and 5.5 mm for the coronary arteries at their origins. The left exceed the right in 60% of hearts, the right being larger in 17%, and both vessels being approximately equal in 23%. The diameters of the coronary arteries may increase up to the 30th year.

Right coronary artery

The right coronary artery arises from the anterior ('right coronary') aortic sinus: the ostium is below the margin of the cusps in 10%. The artery is usually single, but as many as four right coronary arteries have been observed. It passes at first anteriorly and slightly to the right between the right auricle and pulmonary trunk, where the sinus usually bulges. It reaches the atrioventricular groove and descends in this almost vertically to the right (acute) cardiac border, curving around it into the posterior part of the groove, where the latter approaches its junction with both interatrial and interventricular grooves, a region appropriately termed the crux of the heart. The artery reaches the crux and ends a little to the left of it, often by anastomosing with the circumflex branch of the left coronary artery. In a minority of individuals, the right coronary artery ends near the right cardiac border (10%), or between this and the crux (10%); more often (20%) it reaches the left border, replacing part of the circumflex artery.

Branches of the right coronary supply the right atrium and ventricle and, variably, parts of the left chambers and atrioventricular septum. The first branch (arising separately from the anterior aortic sinus in 36% of individuals) is the arteria coni arteriosi or conus artery. This is sometimes termed a ‘third coronary’ artery, but as a similar vessel comes from the left coronary, it is more correctly named the right conus artery. It ramifies anteriorly on the lowest part of the pulmonary conus and upper part of the right ventricle. It may anastomose with a similar left coronary branch from the left anterior descending artery to form the ‘anulus of Vieussens’, which is a tenuous anastomotic ‘circle’ around the right ventricular outflow tract.

The first segment of the right coronary artery (between its origin and the right margin of the heart) gives off anterior atrial and ventricular branches. These vessels diverge widely, approaching a right angle in the case of ventricular arteries, which is in marked
contrast to the more acute origins of the left coronary ventricular branches. The anterior ventricular branches, usually two or three, ramify towards the cardiac apex, which they rarely reach unless the right marginal artery is included in this group of branches, as it is by some authors. The right marginal artery is greater in calibre than the other anterior ventricular arteries and long enough to reach the apex in most hearts (93%). When it is very large, the remaining anterior ventricular branches may be reduced to one, or may be absent. Up to three small posterior ventricular branches, commonly two, arise from the second segment of the right coronary artery between the right border and crux and supply the diaphragmatic aspect of the right ventricle. Their size is inversely proportional to that of the right marginal artery, which usually extends to the diaphragmatic surface of the heart. As the right coronary approaches the crux, it normally produces one to three posterior interventricular branches (occasionally there are none). One, the posterior interventricular artery, lies in the interventricular groove. It is usually single (70%), and flanked either to the right or left or bilaterally by parallel branches from the right coronary artery. When these flanking vessels exist, branches of the posterior interventricular artery are small and sparse. The posterior interventricular artery is replaced by a left coronary branch in 10% of individuals.

Although the atrial branches of the right coronary artery are sometimes described as anterior, lateral (right or marginal) and posterior groups, they are usually small single vessels 1mm in diameter. The right anterior and lateral branches are occasionally double, very rarely triple, and mainly supply the right atrium. The posterior branch is usually single and supplies the right and left atria. The artery of the sinoatrial node is an atrial branch, distributed largely to the myocardium of both atria, mainly the right. Its origin is variable: it comes from the circumflex branch of the left coronary in 35%. However, more commonly it arises from the anterior atrial branch of the right coronary artery, less often from its right lateral part, least often from its posterior atrioventricular part. This 'nodal' artery thus usually passes back in the groove between the right auricular appendage and aorta. Whatever its origin, it usually branches around the base of the superior vena cava, typically as an arterial loop from which small branches supply the right atrium. A large 'ramus crista terminalis' traverses the sinu-atrial node (Fig. 56.18A–C); it would seem more appropriate to name this branch the 'nodal artery', as most of the currently named vessel actually supplies the atria and serves as the 'main atrial branch'.

Septal branches of the right coronary artery are relatively short, and leave the posterior interventricular branch to supply the posterior interventricular septum. They are numerous, but do not usually reach the apical parts of the septum. The largest posterior septal artery, usually the first, commonly arises from the inverted loop which is said to characterize the right coronary artery at the crux. It supplies the atrioventricular node in 80% of hearts.

Small recurrent atrioventricular branches are given off from the ventricular branches of the right coronary artery as they cross the atrioventricular groove; they supply the adjoining atrial myocardium.

Left coronary artery

The left coronary artery is larger in calibre than the right, and supplies a greater volume of myocardium, including almost all the left ventricle and atrium, except in so-
called 'right dominance', when the right coronary artery partly supplies a posterior region of the left ventricle (Fig. 56.18A-C). The left coronary artery usually supplies most of the interventricular septum. It arises from the left posterior (left 'coronary') aortic sinus; the ostium is below the margin of the cusps in 15%, and may be double, leading into major initial branches, usually the circumflex and anterior interventricular (descending) arteries. Its initial portion, between its ostium and its first branches, varies in length from a few millimetres to a few centimetres. The artery lies between the pulmonary trunk and the left atrial auricle, emerging into the atrioventricular groove, in which it turns left. This part is loosely embedded in subepicardial fat and usually has no branches, but may give off a small atrial ramus and, rarely, the sinuatrial nodal artery.

Reaching the atrioventricular groove, the left coronary divides into two or three main branches: the anterior interventricular artery is commonly described as its continuation. This artery descends obliquely forward and to the left in the interventricular groove, sometimes deeply embedded in or crossed by bridges of myocardial tissue, and by the great cardiac vein and its tributaries. Almost invariably, it reaches the apex. It terminates there in one-third of specimens, but more often it turns round the apex into the posterior interventricular groove, and passes one-third to one-half of the way along its length, where it meets the terminal twigs of the posterior interventricular branches of the right coronary artery.

The anterior interventricular artery produces right and left anterior ventricular and anterior septal branches, and a variable number of corresponding posterior branches. Anterior right ventricular branches are small and rarely number more than one or two; the right ventricle is supplied almost wholly by the right coronary artery.

From two to nine large left anterior ventricular arteries branch at acute angles from the anterior interventricular artery and cross the anterior aspect of the left ventricle diagonally; larger terminals reach the rounded (obtuse) left border. One is often large and may arise separately from the left coronary trunk, which then ends by trifurcation. This left diagonal artery, reported in 33–50% or more individuals, is sometimes duplicated (20%). A small left conus artery frequently leaves the anterior interventricular artery near its origin, and anastomoses on the conus with its counterpart from the right coronary artery and with the vasa vasorum of the pulmonary artery and aorta. The anterior septal branches leave the anterior interventricular artery almost perpendicularly, and pass back and down in the septum, usually supplying its ventral two-thirds. Small posterior septal branches from the same source supply the posterior one-third of the septum for a variable distance from the cardiac apex.

The circumflex artery, comparable to the anterior interventricular artery in calibre, curves left in the atrioventricular groove, continuing round the left cardiac border into the posterior part of the groove and ending left of the crux in most hearts, but sometimes continuing as a posterior interventricular artery. Proximally, the left atrial auricle usually overlaps it. In 90%, a large ventricular branch, the left marginal artery, arises perpendicularly from the circumflex artery and ramifies over the rounded ‘obtuse’ margin, supplying much of the adjacent left ventricle, usually to the apex. Smaller anterior and posterior branches of the circumflex artery also supply the left ventricle. Anterior ventricular branches (from one to five, commonly two or three) course parallel to the diagonal artery, when it is present, and replace it when it is absent. Posterior ventricular branches are smaller and fewer; the left ventricle is partly
supplied by the posterior interventricular artery. When this is small or absent, it is accompanied or replaced by an interventricular continuation of the circumflex artery, which is frequently double or triple. The circumflex artery may supply the left atrium via anterior, lateral and posterior atrial branches.

The circumflex artery has inconstant branches. The artery to the sino-atrial node (35%) is usually derived from the anterior circumflex segment, less often from the circum-marginal. It passes over and supplies the left atrium, encircling the superior vena cava like a right coronary nodal branch. It sends a large branch to (and through) the node, but is predominantly atrial in distribution. The artery to the atrioventricular node, the terminal branch in 20%, arises near the crux, in which case the circumflex usually supplies the posterior interventricular artery, an example of so-called 'left dominance'. Kugel's anastomotic artery ('arteria anastomotica auricularis magna') has been described as a constant circumflex branch, usually from its anterior part, which traverses the interatrial septum (near its ventricular border) to establish direct or indirect anastomosis with the right coronary; its existence has been questioned.

**Coronary distribution**

Details of coronary distribution require integration into a concept of total cardiac supply. Most commonly, the right coronary artery supplies all of the right ventricle (except a small region to the right of the anterior interventricular groove); a variable part of the diaphragmatic aspect of the left ventricle; the posteroinferior one-third of the intraventricular septum; the right atrium and part of the left atrium; the conduction system as far as the proximal parts of the right and left crura. Left coronary distribution is reciprocal, and includes most of the left ventricle; a narrow strip of right ventricle; the anterior two-thirds of the interventricular septum; most of the left atrium. As noted previously (Fig. 56.18A–E), variations in the coronary arterial system mainly affect the diaphragmatic aspect of the ventricles and reflect the relative 'dominance' of supply by the left or the right coronary artery. The term is misleading, because the left artery almost always supplies a greater volume of tissue than the right. In 'right dominance', the posterior interventricular artery is derived from the right coronary artery; in 'left dominance' it is derived from the left coronary artery. In the so-called 'balanced' pattern, branches of both arteries run in or near the posterior interventricular groove.

Less is known about variations in atrial supply because the small vessels involved are not easily preserved in the corrosion casts that are used for analysis. In more than 50% of individuals, the right atrium is supplied only by the right coronary artery, and in the remainder the supply is dual. More than 62% of left atria are supplied mainly by the left coronary artery, 27% by the right coronary artery (in each group a small accessory supply from the other coronary artery exists), and 11% are supplied almost equally by both arteries. Sinu-atrial and atrioventricular supplies also vary. The sinu-atrial node is supplied by the right (51–65%) or left (35–45%) coronary arteries, and fewer than 10% of nodes receive a bilateral supply. The atrioventricular node is supplied by the right (80–90%) or left (10–20%) coronary arteries.

**Coronary anastomosis**

Anastomoses between branches of the coronary arteries, both subepicardial and myocardial, and between these arteries and extracardiac vessels, are of prime medical importance. Clinical experience suggests that anastomoses cannot rapidly
provide collateral routes sufficient to circumvent sudden coronary obstruction, and the
 coronary circulation is assumed to be end-arterial. Nevertheless, it has long been
 established that anastomoses do occur, particularly between fine subepicardial
 branches, and they may increase during individual life. Analyses of coronary
 radiographs and resin corrosion casts, and the results of radio-opaque perfusion
 studies, have revealed intra- and inter-coronary anastomoses in vessels up to 100–
 200 µm in calibre. The most frequent sites of extramural anastomoses are the apex,
 the anterior aspect of the right ventricle, the posterior aspect of the left ventricle, crux,
 interatrial and interventricular grooves, and between the sinoatrial nodal and other
 atrial vessels. The functional value of such anastomoses must vary, but they appear
to become more effective in slowly progressive pathological conditions. Their structure
 is uncertain: most observations that have been made on corrosion casts suggest that
 anastomotic vessels are relatively straight in normal hearts, but greatly coiled in hearts
 that have been subject to coronary occlusion. Little has been recorded of their
 microscopic structure; they appear little more than endothelial tubes, without muscles
 or elastic tissue.

Extracardiac anastomoses may connect various coronary branches with other thoracic
 vessels via the pericardial arteries and arterial vasa vasora of vessels which link the
 heart with the systemic and pulmonary circulations. The effectiveness of these
 connections as collateral routes in coronary occlusion is unpredictable.

Coronary arteriovenous anastomoses and numerous connections between the
 coronary circulation and cardiac cavities, producing so-called ‘myocardial sinusoids'
 and ‘arterioluminal' vessels, have been reported; their importance in coronary disease
 is uncertain.

Coronary artery disease

Atherosclerosis is characterized by deposition of lipid and accumulation of
 macrophages in the intima. Endothelial dysfunction leads to the recruitment of
 inflammatory cells into the vascular wall and the release of various cytokines and
 adhesion molecules which propagate the process of atherosclerosis. Lipid
 accumulation and smooth muscle proliferation lead to the formation of an
 atheromatous plaque. The formation of the plaque itself may cause stenosis of the
 coronary arteries, and reduces coronary blood flow (classically on exertion). The
 plaques are also susceptible to rupture with concomitant thrombus formation, which
 leads to acute occlusion of one of the coronary arteries and may cause myocardial
 infarction. Plaques may rupture as a result of fatigue within the fibrous cap, but are
 also more vulnerable when the lipid content is greater than 40% of the composition of
 the plaque. Superficial erosion of the plaque may also promote critical thrombus
 formation.

Assessment of coronary artery disease is possible via a number of radiological
 techniques, including MRI, positron emission tomography, scintigraphy and
 ultrasound, and invasively by coronary arteriography (which displays the anatomy and
delineates regions of stenosis).

Coronary angiography

Coronary angiography may be performed by introducing a catheter through the
 femoral, radial or brachial arteries. The femoral artery is punctured with a needle 3 cm
below the inguinal ligament while the leg is held adducted and slightly externally rotated. The exact position is guided by palpation of the femoral arterial pulse, and the needle is inserted at an angle of 45°. After arterial puncture, a fine guidewire is inserted through the needle and fed into the artery. The catheter is then inserted over the guidewire and manipulated via the iliac artery into the aorta, up the aortic arch and located in the ascending aorta. The brachial or radial artery may be used for percutaneous access to the circulation. Once the catheter is located in the ascending aorta, a variety of guidewires (straight tip, left and right curved catheters, and pigtail catheters) are used to enter the coronary vessels for selective arteriography and interventions. Angiography is performed with standard high osmolality contrast medium with cineangiography. In selected patients, new-generation low osmolality contrast medium may also be used. All the coronary arteries are catheterized and evaluated in a variety of views to obtain a full evaluation of their anatomy and to determine the location and degree of any stenoses. The ostium of the left coronary artery arises from the left sinus and is best viewed in the direct frontal and left anterior oblique directions. The right anterior oblique view is useful in demonstrating the diagonal branches and anterior interventricular (descending) coronary artery. The right coronary artery originates from the right sinus of Valsalva and is usually visualized in the right anterior oblique and left anterior oblique views. Pressure and oxygen saturations can be measured via the catheter. Changes in pressure across valves allow the degree of stenosis to be measured. Coronary blood flow and relative flow reserve can also be calculated. Significant stenosis may be treated initially by balloon angioplasty followed by insertion of stents. The balloon exerts pressure against the plaque in the arterial wall and fractures and splits the plaque. The splinting effect of the plaque and elastic recoil are reduced, resulting in an increase in the arterial lumen. Insertion of a stent reduces the rate of re-stenosis.

**Coronary revascularization**

Atherosclerosis causing greater than 60% stenosis of the terminal diameter of the coronary arteries is likely to cause a significant reduction in myocardial perfusion. Patients with high-grade lesions or left main-stem coronary artery or triple-vessel disease with impaired left ventricular function are usually considered for coronary artery bypass grafting. The common grafts that are used are the saphenous veins and internal thoracic (mammary) arteries. Other grafts that are occasionally used are the radial, ulnar, gastroepiploic and inferior epigastric arteries.

The left internal thoracic artery grafts have a greater patency rate than saphenous vein grafts. Approximately 15% of saphenous vein grafts occlude in 1 year and from then on at an annual rate of 1–2% in the first 6 years and 4% thereafter; 40–50% of saphenous vein grafts have occluded by 10 years. In contrast, only about 10% of left internal thoracic artery grafts will have occluded at 10 years.

The common surgical approach is via a midline sternotomy. If the internal thoracic artery is used as a donor graft, it is divided distally (maintaining its proximal origin from the subclavian artery) and anastomosed to the coronary artery distal to the stenosis. If saphenous vein grafts are used, they must be anastomosed both proximal and distal to the coronary artery, to bridge the site of the stenosis.

In selected cases, minimally invasive direct coronary artery bypass grafting is performed, but the approach is dependent on the vessel being grafted. The anterior
approach is via mini-thoracotomy over the fourth intercostal space underneath the
nipple for grafting the mid-left anterior interventricular (descending) and diagonal
branches. The anterolateral approach is via an incision in the third intercostal space
from the midclavicular line to the anterior axillary line and is used for grafting early
marginal branches of the circumflex system. The lateral approach allows grafting of
the circumflex vessels via a lateral thoracotomy measuring only 10 cm in size through
the fifth or sixth intercostal space. Extrathoracic approaches that are occasionally
used include the subxiphoid approach for the distal right coronary artery and posterior
interventricular (descending) artery. Port access surgery allows for full re-
vascularization with cardiopulmonary bypass, but obviates the need for midline
sternotomy.

**Cardiac veins**

The heart is drained by the coronary sinus and its tributaries, the anterior cardiac
veins and the small cardiac veins. The coronary sinus and its tributaries return blood
to the right atrium from the entire heart (including its septa) except for the anterior
region of the right ventricle and small, variable parts of both atria and the left ventricle.
The anterior cardiac veins drain an anterior region of the right ventricle and, when the
right marginal vein joins this group, a region around the right cardiac border, and end
principally in the right atrium. The small cardiac veins (Thebesius' veins) open into the
right atrium and ventricle and, to a lesser extent, the left atrium and sometimes the left
ventricle.

**Variation in cardiac veins**

Attempts to categorize variations in cardiac venous circulation into ‘types' have not
produced any accepted pattern. There are major variations concerning the general
directions of drainage. The coronary sinus may receive all the cardiac veins (except
the small veins), including the anterior cardiac veins (33%), which may be reduced by
diversion of some into the small cardiac vein and then to the coronary sinus (28%).
The remainder (39%) represents the ‘normal' pattern, as described above.

**Coronary sinus**

The large majority of cardiac veins drain into the wide coronary sinus, 2 or 3 cm long,
lying in the posterior atrioventricular groove between the left atrium and ventricle (Fig.
56.2B,D; Fig. 56.19). The sinus opens into the right atrium between the opening of the
inferior vena cava and the right atrioventricular orifice; the opening is guarded by an
endocardial fold (semilunar valve of the coronary sinus; Fig. 56.4A). Its tributaries are
the great, small and middle cardiac veins, the posterior vein of the left ventricle and
the oblique vein of the left atrium; all except the last have valves at their orifices.
The great cardiac vein begins at the cardiac apex, ascends in the anterior interventricular groove to the atrioventricular groove and follows this, passing to the left and posteriorly to enter the coronary sinus at its origin (Fig. 56.19). It receives tributaries from the left atrium and both ventricles, including the large left marginal vein that ascends the left aspect (obtuse border) of the heart.

Small cardiac vein

The small cardiac vein lies in the posterior atroventricular groove between the right atrium and ventricle and opens into the coronary sinus near its atrial end (Fig. 56.19). It receives blood from the posterior part of the right atrium and ventricle. The right marginal vein passes right, along the inferior cardiac margin (acute border). It may join the small cardiac vein in the atrioventricular groove, but more often opens directly into the right atrium.

Middle cardiac vein

The middle cardiac vein (Fig. 56.19) begins at the cardiac apex, and runs back in the posterior interventricular groove to end in the coronary sinus near its atrial end.

Posterior vein of the left ventricle

The posterior vein of the left ventricle (Fig. 56.19) is found on the diaphragmatic surface of the left ventricle a little to the left of the middle cardiac vein. It usually opens into the centre of the coronary sinus, but sometimes opens into the great cardiac vein.
Oblique vein of the left atrium

The small vessel that is the oblique vein of the left atrium (Fig. 56.19) descends obliquely on the back of the left atrium to join the coronary sinus near its end. It is continuous above with the ligament of the left vena cava. The two structures are remnants of the left common cardinal vein.

Anterior cardiac veins

The anterior cardiac veins drain the anterior part of the right ventricle (Figs 56.2A,C; 56.8). Usually two or three, sometimes even five, they ascend in subepicardial tissue to cross the right part of the atrioventricular groove, passing deep or superficial to the right coronary artery. They end in the right atrium, near the groove, separately or in variable combinations. A subendocardial collecting channel, into which all may open, has been described. The right marginal vein courses along the inferior (acute) cardiac margin, draining adjacent parts of the right ventricle, and usually opens separately into the right atrium. It may join the anterior cardiac veins or, less often, the coronary sinus. Because it is commonly independent, it is often grouped with the small cardiac veins, but it is larger in calibre, being comparable to the anterior cardiac veins or even wider.

Small cardiac veins

The existence of small cardiac veins, opening into all cardiac cavities, has been confirmed, but they are more difficult to demonstrate than larger cardiac vessels. Their numbers and size are highly variable: up to 2 mm in diameter opening into the right atrium and 0.5 mm into the right ventricle. Numerous small cardiac veins have been identified in the right atrium and ventricle, but they are rare in the left atrium and left ventricle.

Cardiac venous anastomosis

There are widespread anastomoses at all levels of the cardiac venous circulation, on a scale exceeding that of the arteries and amounting to a veritable venous plexus. Not only are adjacent veins often connected, but connections also exist between tributaries of the coronary sinus and those of the anterior cardiac veins. Abundant anastomoses occur at the apex and its anterior and posterior aspects. Like coronary arteries, cardiac veins connect with extracardiac vessels, chiefly the vasa vasorum of the large vessels continuous with the heart.

Lymphatic drainage of the heart

Cardiac lymphatic vessels form subendocardial, myocardial and subepicardial plexuses, the first two draining into the third. Efferents from the subepicardial plexuses form the left and right cardiac collecting trunks. Two or three left trunks ascend the anterior interventricular groove, receiving vessels from both ventricles. On reaching the atrioventricular groove, they are joined by a large vessel from the diaphragmatic surface of the left ventricle, which first ascends in the posterior interventricular groove and then turns left along the atrioventricular groove. The vessel formed by this union ascends between the pulmonary artery and the left atrium, and usually ends in an inferior tracheobronchial node. The right trunk receives afferents from the right atrium and the right border and diaphragmatic surface of the right ventricle. It ascends in the
atrioventricular groove, near the right coronary artery, and then anterior to the ascending aorta to end in a brachiocephalic node, usually on the left.
INNERVATION

Initiation of the cardiac cycle is myogenic, originating in the sinu-atrial node. It is harmonized in rate, force and output by autonomic nerves which operate on the nodal tissues and their prolongations, on coronary vessels and on the working atrial and ventricular musculature. All the cardiac branches of the vagus (parasympathetic) and all the sympathetic branches (except the cardiac branch of the superior cervical sympathetic ganglion) contain both afferent and efferent fibres; the cardiac branch of the superior cervical sympathetic ganglion is entirely efferent. Sympathetic fibres accelerate the heart and dilate the coronary arteries when stimulated, whereas vagal fibres slow the heart and cause constriction of the coronary arteries.

Preganglionic cardiac sympathetic axons arise from neurones in the intermediolateral column of the upper four or five thoracic spinal segments. Some synapse in the corresponding upper thoracic sympathetic ganglia, others ascend to synapse in the cervical ganglia; postganglionic fibres from these ganglia form the sympathetic cardiac nerves.

Preganglionic cardiac parasympathetic axons arise from neurones in either the dorsal vagal nucleus or near the nucleus ambiguus; they run in vagal cardiac branches to synapse in the cardiac plexuses and atrial walls. In man (like most mammals) intrinsic cardiac neurones are limited to the atria and interatrial septum, and are most numerous in the subepicardial connective tissue near the sinu-atrial and atrioventricular nodes. There is evidence that these intrinsic ganglia are not simple nicotinic relays, but may act as sites for integration of extrinsic nervous inputs and form complex circuits for the local neuronal control of the heart, and perhaps even local reflexes.

Cardiac plexus

Nearing the heart, the autonomic nerves form a mixed cardiac plexus, usually described in terms of a superficial component inferior to the aortic arch lying between it and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation. The cardiac plexus is also described by regional names for its coronary, pulmonary, atrial and aortic extensions (Fig. 56.20). These plexuses contain ganglion cells. Ganglion cells, confined to the atrial tissues, and with a preponderance adjacent to the sinu-atrial node, are also found in the heart along the distribution of branches of the plexus. Their axons are considered to be largely, if not exclusively, postganglionic parasympathetic. Cholinergic and adrenergic fibres, arising in or passing through the cardiac plexus, are distributed most profusely to the sinu-atrial and atrioventricular nodes; the supply to the atrial and ventricular myocardium is much less dense. Adrenergic fibres supply the coronary arteries and cardiac veins. Rich plexuses of nerves containing cholinesterase, adrenergic transmitters and other peptides, e.g. neuropeptide
Y, are found in the subendocardial regions of all chambers and in the cusps of the valves.

**Superficial (ventral) part of the cardiac plexus**

The superficial (ventral) part of the cardiac plexus lies below the aortic arch and anterior to the right pulmonary artery. It is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the lower of the two cervical cardiac branches of the left vagus. A small cardiac ganglion is usually present in this plexus immediately below the aortic arch, to the right of the ligamentum arteriosum. This part of the cardiac plexus connects with the deep part, the right coronary plexus and the left anterior pulmonary plexus.

**Deep (dorsal) part of the cardiac plexus**

The deep (dorsal) part of the cardiac plexus is anterior to the tracheal bifurcation, above the point of division of the pulmonary trunk and posterior to the aortic arch. It is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the plexus.

Branches from the right half of the deep part of the cardiac plexus pass in front of and behind the right pulmonary artery. Those anterior to it, the more numerous, supply a few filaments to the right anterior pulmonary plexus and continue on to form part of the right coronary plexus. Those behind the pulmonary artery supply a few filaments to the right atrium and then continue into the left coronary plexus. The left half of the deep part of the cardiac plexus is connected with the superficial, and supplies filaments to the left atrium and left anterior pulmonary plexus. It forms much of the left coronary plexus.

**Left coronary plexus**

The left coronary plexus is larger than the right, and is formed chiefly by the prolongation of the left half of the deep part of the cardiac plexus and a few fibres from the right. It accompanies the left coronary artery to supply the left atrium and ventricle.

**Right coronary plexus**

The right coronary plexus is formed from both superficial and deep parts of the cardiac plexus, and accompanies the right coronary artery to supply the right atrium and ventricle.

**Atrial plexuses**
The atrial plexuses are derivatives of the right and left continuations of the cardiac plexus along the coronary arteries. Their fibres are distributed to the corresponding atria, overlapping those from the coronary plexuses.
MAJOR BLOOD VESSELS

The major blood vessels comprise the pulmonary trunk, the thoracic aorta and its branches, the superior and inferior venae cavae and their tributaries.

ARTERIES

Pulmonary trunk

The pulmonary trunk, or pulmonary artery, conveys deoxygenated blood from the right ventricle to the lungs (Fig. 56.2A,C; see Fig. 57.8). About 5 cm in length and 3 cm in diameter, it is the most anterior of the cardiac vessels and arises from the base of the right ventricle (from the pulmonary anulus surmounting the conus arteriosus) above and to the left of the supraventricular crest. It slopes up and back, at first in front of the ascending aorta, then to its left. Below the aortic arch it divides, level with the fifth thoracic vertebra and to the left of the midline, into right and left pulmonary arteries of almost equal size. The pulmonary trunk bifurcation lies below, in front and to the left of the tracheal bifurcation (which is also associated with the inferior tracheobronchial lymph nodes and the deep cardiac nerve plexus). In the fetus, at the level of the bifurcation the pulmonary artery is connected to the aortic arch by the ductus arteriosus, which lies in the same direction as the pulmonary artery.

Relations

The pulmonary artery is entirely within the pericardium, enclosed with the ascending aorta in a common tube of visceral pericardium. The fibrous pericardium gradually disappears within the adventitia of the pulmonary arteries. Anteriorly, it is separated from the eternal end of the left second intercostal space by the pleura, left lung and pericardium. Posterior are the ascending aorta and left coronary artery initially, then the left atrium. The ascending aorta ultimately lies on its right. An auricle and coronary artery lie on each side of its origin. The superficial cardiac plexus is between the pulmonary bifurcation and the aortic arch. The tracheal bifurcation, lymph nodes and nerves are above, bilateral and right.

During fetal life, when blood pressure is similar in the pulmonary artery and the aorta, the structure of the vessels is similar. After birth, the lungs expand and pulmonary arterioles dilate, and so pulmonary vascular resistance decreases, whereas blood flow increases. The systolic pressure in the pulmonary artery consequently decreases and this is accompanied by a structural remodelling of its wall. The elastic material, which originally had a lamellar structure, becomes aggregated into star-shaped units linked to many muscle cells. The amount of muscular tissue grows extensively after birth and exceeds that found in the aorta. The thickness of the wall of the aorta is about twice that of the pulmonary artery.

Right and left pulmonary arteries

The pulmonary arteries are described on page 996.

Thoracic aorta

Ascending aorta
The ascending aorta is typically 5 cm long and begins at the base of the left ventricle, level with the lower border of the third left costal cartilage; it ascends obliquely, curving forwards and to the right, behind the left half of the sternum to the level of the upper border of the second left costal cartilage (Figs 56.2A, B, 56.8, 56.18A–C; see Figs 53.2, 57.8). At its origin, proximal to the aortic anulus, the sectional profile is larger and not circular because of three almost hemispherical outward bulges (sinuses of Valsalva), one posterior (non-coronary), one left and one right, which correspond to the three cusps of the aortic valve (see above). Distal to the aortic anulus there are three aortic sinuses, beyond which the calibre of the vessel is slightly increased by a bulging of its right wall. This aortic bulb gives the vessel an oval section.

Relations

The ascending aorta is within the fibrous pericardium, enclosed in a tube of serosal pericardium with the pulmonary trunk (Figs 56.1, 56.2A,C). Anterior to its lower part are the infundibulum, the initial segment of the pulmonary trunk and the right auricle. Superiorly, it is separated from the sternum by the pericardium, right pleura, anterior margin of the right lung, loose areolar tissue and the remains of the thymus gland. Posterior are the left atrium, right pulmonary artery and principal bronchus. Right lateral are the superior vena cava and right atrium, the former partly posterior, and left lateral are the left atrium and, at a higher level, the pulmonary trunk. At least two structures, aorticopulmonary bodies (reminiscent of the carotid arterial chemoreceptors and baroreceptors), lie between the ascending aorta and the pulmonary trunk. The inferior aorticopulmonary body is near the heart and anterior to the aorta, and the middle aorticopulmonary body is near the right side of the ascending aorta.

Aortic arch

The aortic arch continues from the ascending aorta (Figs 56.1, 56.2A,C). Its origin, slightly to the right, is level with the upper border of the second right sternocostal joint. The arch first ascends diagonally back and to the left over the anterior surface of the trachea, then back across its left side and finally descends to the left of the fourth thoracic vertebral body, continuing as the descending thoracic aorta. It ends level with the sternal end of the second, left costal cartilage. Thus the aortic arch lies wholly in the superior mediastinum. It curves around the hilum of the left lung, and extends upwards to the mid level of the manubrium of the sternum. The shadow of the arch is easily identified in anteroposterior radiographs and its left profile is sometimes called the ‘aortic knuckle’ (see Fig. 55.16). The arch may also be visible in left anterior oblique views enclosing a pale space, ‘the aortic window’, in which shadows of the pulmonary trunk and its left branch may be discerned. Its diameter at the origin is the same as in the ascending aorta, 28 mm, but it is reduced to 20 mm at the end, after the issue of its large collateral branches. At the border with the thoracic aorta, a small stricture (aortic isthmus), followed by a dilatation, can be recognized. In fetal life the isthmus lies between the origin of the left subclavian artery and the opening of the ductus arteriosus.

Relations

Anteriorly and to the left of the aortic arch is the left mediastinal pleura. Deep to the pleura it is crossed, in anteroposterior order by: the left phrenic nerve, left lower cervical cardiac branch of the vagus, left superior cervical cardiac branch of the
sympathetic and left vagus (Figs 56.1, 56.20). As the left vagus crosses the arch, its recurrent laryngeal branch hooks below the vessel left and behind (developmentally caudal to) the ligamentum arteriosum and then ascends on the right of the arch. The left superior intercostal vein ascends obliquely forwards on the arch, superficial to the left vagus, deep to the left phrenic nerve. The left lung and pleura separate all these from the thoracic wall. Posterior and to the right are the trachea and deep cardiac plexus, the left recurrent laryngeal nerve, oesophagus, thoracic duct and vertebral column. Above, the brachiocephalic, left common carotid and left subclavian arteries arise from its convexity, and are crossed anteriorly near their origins by the left brachiocephalic vein. Below are the pulmonary bifurcation, left principal bronchus, ligamentum arteriosum, superficial cardiac plexus and left recurrent laryngeal nerve. Best viewed from the left, the concavity of the aortic arch is the upper curved limit through which structures gain access to or leave the hilum of the left lung.

Variations of the arch and its branches

The summit of the arch is usually about 2.5 cm below the suprasternal border, but may diverge from this. In the infant it is closer to the upper border of the sternum; the same is often the case in old age, because of the dilatation of the vessel. Sometimes the aorta curves over the right pulmonary hilum and descends to the right of the vertebral column. This is usually accompanied by transposition of thoracic and abdominal viscera. Less often, after arching over the right hilum, it passes behind the oesophagus to gain its usual position (this is not accompanied by visceral transposition). The aorta may divide into ascending and descending trunks, the former dividing into three branches to supply the head and upper limbs. Sometimes it divides near its origin, the two branches soon reuniting, and the oesophagus and trachea usually pass through the interval between them.

Branches

Three branches arise from the convex aspect of the arch: the brachiocephalic trunk, left common carotid and left subclavian arteries (Figs 56.1, 56.2A–D). They may branch from the beginning of the arch or the upper part of the ascending aorta. The distance between these origins varies, the most frequent being approximation of the left common carotid artery to the brachiocephalic trunk.

Primary branches from the aortic arch may be reduced to one, but more commonly two. The left common carotid may arise from the brachiocephalic trunk (7%). More rarely, the left common carotid and subclavian arteries may arise from a left brachiocephalic trunk, or the right common carotid and right subclavian may arise separately, in which case the latter more often branches from the left end of the arch and passes behind the oesophagus. The left vertebral artery may arise between the left common carotid and the subclavian arteries. Very rarely, external and internal carotid arteries arise separately, the common carotid being absent on one or both sides, or both carotids and one or both vertebral arteries may be separate branches. When a ‘right aorta’ occurs, the arrangement of its three branches is reversed. The common carotids may have a single trunk. Other arteries may branch from it, most commonly one or both bronchial arteries and the thyroid ima artery.

An analysis of variation in branches from 1000 aortic arches showed the usual pattern in 65%; a left common carotid shared the brachiocephalic trunk in 27% (contrast percentage quoted above) and the four large arteries branched separately in 2.5%.
The remaining 5% showed a great variety of patterns, the most common (1.2%) being symmetric right and left brachiocephalic trunks.

**Coarctation of the aorta**

The aortic lumen is occasionally partly or completely obliterated, either above (preductal or infantile type), opposite, or just beyond (postductal or adult type), the entry of the ductus arteriosus. In the preductal type, the length of coarctation is variable, aortic arch hypoplasia is common and the left subclavian and even the brachiocephalic artery may be involved. Severe forms of infantile coarctation and its extreme form (aortic interruption) may be patent ductus arteriosus dependent, as there is no time for effective collateral circulation to develop. Prostaglandin infusion prior to transfer, and surgery at a tertiary centre, often provide a very good mid- to long-term outlook for such infants.

The postductal type of coarctation has been attributed to abnormal extension of the ductal tissue into the aortic wall, stenosing both vessels as the duct contracts after birth. This form can permit years of normal life, allowing the development of an extensive collateral circulation to the aorta distal to the stenosis (Fig. 56.21). High vascularity of the thoracic wall is important and clinically characteristic; many arteries arising indirectly from the aorta, proximal to the coarctation segment, anastomose with vessels connected with it distal to the block, and all of these vessels become greatly enlarged. Thus, in the anterior thoracic wall, the thoraco-acromial, lateral thoracic and subscapular arteries (from the axillary artery), the suprascapular artery (from the subclavian artery), and the first and second posterior intercostal arteries (from the costocervical trunk), anastomose with other posterior intercostal arteries, and the internal thoracic artery and its terminal branches anastomose with the lower posterior intercostal and inferior epigastric arteries. Posterior intercostal arteries are always involved, and enlargement of their dorsal branches may eventually groove (‘notch’) the inferior margins of the ribs. The radiographic shadow of the enlarged left subclavian artery is also increased. Enlargement of the scapular vessels and anastomoses may lead to widespread interscapular pulsation (easily appreciated with the palm of the hand, and sometimes heard on auscultation).
Aortic aneurysm formation

An aneurysm (abnormal dilatation) may form in any part of the aorta. Degeneration of the medial wall of the aorta and intimal dissection occur in the majority of thoracic aneurysms, particularly affecting the ascending aorta and aortic arch. These are often the result of abnormalities of connective tissue such as occur in Marfan's syndrome, homocysteinuria and Ehlers–Danlos syndrome, or may relate to a bicuspid aortic valve or be secondary to syphilis. Descending aortic aneurysms are generally caused by atherosclerosis (90%); the remainder result from mycotic disease or trauma. Some aortic aneurysms are incidental findings on chest X-rays or computed tomography scans. Symptomatic cases present with breathlessness, chest pain, back pain, hoarse
voice, cough and haemoptysis. Early diastolic murmurs may be audible on cardiac auscultation and are caused by aortic regurgitation. Repair is carried out in patients with symptoms or fusiform dilatation measuring more than 5 cm in diameter.

**Aortic dissection**

Aortic dissection occurs as a result of degeneration of the medial aspect of the aortic wall as a result of ageing, persistent hypertension or in fibrillin diseases such as Marfan's disease. An intimal tear may occur, producing a split into the medial wall, which creates a false lumen. These cases present acutely with severe retrosternal or intrascapular chest pain. Depending on the extent of the dissection, they may be associated with neurological signs, diarrhoea or leg weakness. Extension into the pericardium causes cardiac tamponade and circulatory collapse. Diagnosis is established by echocardiography and on contrast-enhanced computed tomography or magnetic resonance scans. Surgical repair is essential for ascending aortic or aortic arch dissection.

**Brachiocephalic artery**

The brachiocephalic (innominate) artery, the largest branch of the aortic arch, is 4–5 cm in length (Fig. 56.2A,C; see Fig. 28.14). It arises from the convexity of the arch posterior to the centre of the manubrium of sternum, and ascends posterolaterally to the right, at first anterior to the trachea, then on its right. Level with the upper border of the right sternoclavicular joint, it divides into the right common carotid and right subclavian arteries.

**Relations**

Sternohyoid and sternothyroid, the remains of the thymus, left brachiocephalic and right inferior thyroid veins, crossing its root, and sometimes the right cardiac branches of the vagus, all separate the brachiocephalic artery from the manubrium. Posterior are the trachea (superiorly) and the right pleura (inferiorly). The right vagus is posterolateral before passing lateral to the trachea. Right lateral are the right brachiocephalic vein, the upper part of the superior vena cava and pleura, and left lateral are the thymic remains, the origin of the left common carotid artery, the inferior thyroid veins and the trachea.

**Branches**

The brachiocephalic artery usually has only terminal branches, the right common carotid and right subclavian artery. Occasionally a thymic or bronchial branch, or a thyroidea ima artery, arises from it. The thyroidea ima artery is a small and inconstant artery which may arise from the aorta, right common carotid, subclavian or internal thoracic arteries; it ascends on the trachea to the thyroid isthmus, where it terminates.

**Descending thoracic aorta**

The thoracic aorta is the segment of descending aorta confined to the posterior mediastinum (see Fig. 55.4B). It begins level with the lower border of the fourth thoracic vertebra, continuous with the aortic arch, and ends anterior to the lower border of the 12th thoracic vertebra in the diaphragmatic aortic aperture. At its origin it is left of the vertebral column, as it descends it approaches the midline, and at its
termination is directly anterior to it.

Relations

Anterior to the descending thoracic aorta, from above down, are the left pulmonary hilum, the pericardium separating it from the left atrium, oesophagus and diaphragm. Posterior are the vertebral column and hemiazygos veins. Right lateral are the azygos and thoracic duct and below, the right pleura and lung, and left lateral are the pleura and lung. The oesophagus, with its plexus of nerves, is right lateral above, but becomes anterior in the lower thorax, and close to the diaphragm it is left anterolateral. To a limited degree, the descending aorta and oesophagus are mutually spiralized.

Surface anatomy

The descending thoracic aorta may be projected as a 2.5 cm broad band from the sternal end of the second left costal cartilage to a median position 2 cm above the transpyloric plane.

Branches

The thoracic aorta provides visceral branches to the pericardium, lungs, bronchi and oesophagus, and parietal branches to the thoracic wall.

Pericardial branches

A few small vessels are distributed to the posterior aspect of the pericardium.

Bronchial arteries

Bronchial arteries vary in number, size and origin. There is usually only one right bronchial artery which arises either from the third posterior intercostal or upper left bronchial artery, and runs posteriorly on the right bronchus. Its branches supply these structures, in addition to the pulmonary areolar tissue and the bronchopulmonary lymph nodes, pericardium and oesophagus. The left bronchial arteries, usually two, arise from the thoracic aorta, the upper near the fifth thoracic vertebra, the lower below the left bronchus, and run posteriorly to the left bronchus; they are distributed as on the right.

Mediastinal branches

Numerous small vessels supply lymph nodes and areolar tissue in the posterior mediastinum.

Phrenic branches

Phrenic branches arise from the lower thoracic aorta and are distributed posteriorly to the superior diaphragmatic surface. They anastomose with the musculophrenic and pericardiacophrenic arteries.

Posterior intercostal arteries

The posterior intercostal arteries and their branches are described in Chapter 54.
Subcostal arteries

Subcostal arteries are the last paired branches of the thoracic aorta, in series with the posterior intercostal arteries, and below the twelfth ribs. Each runs laterally anterior to the twelfth thoracic vertebral body and posterior to the splanchnic nerves, sympathetic trunk, pleura and diaphragm. The right is also posterior to the thoracic duct and azygos vein, the left is posterior to the accessory hemiazygos vein. Each then enters the abdomen at the lower border of the 12th rib, accompanied by the 12th thoracic (subcostal) nerve, lying posterior to the lateral arcuate ligament and kidney, and anterior to quadratus lumborum. The right artery courses posterior to the ascending colon, the left posterior to the descending colon. Piercing the aponeurosis of transversus abdominis, each proceeds between this and internal oblique, and anastomoses with the superior epigastric, lower posterior intercostal and lumbar arteries. Each has a dorsal branch, distributed like those of the posterior intercostal arteries.

Aberrant artery

A small artery sometimes leaves the thoracic aorta on its right near the right bronchial artery origin. It ascends to the right behind the trachea and oesophagus and may anastomose with the right superior intercostal. It is a vestige of the right dorsal aorta; occasionally it is enlarged as the first part of a right subclavian artery.

Aortic rupture in trauma

Aortic rupture resulting from blunt trauma is a life-threatening injury. It commonly occurs in road traffic accidents and has a poor survival rate of 20%. There is usually a transverse tear in the wall of the aorta, which may involve the intima through to the media of the aorta. The pressure within the systemic circulation may itself cause the formation of a false aneurysm. Rupture of the isthmus region of the descending aorta is more common, probably because the isthmus tends to be the junction between the mobile and fixed portions of the aorta. Other sites include the ascending aorta proximal to the origin of the brachiocephalic artery, the aortic arch and the abdominal aorta. Rupture is likely to be the result of a number of factors, including torsion and shear and stretching forces, and is possibly compounded by hydrostatic pressure.

Aortic atherosclerosis or calcification

Aortic sclerosis or calcification may be implicated in embolic events and strokes. Echocardiography, and particularly transoesophageal echocardiography, allows very detailed assessment of the proximal aorta. The extent of turbulent flow appears as signal loss in the ascending aorta using MRI, and can be used to assess any functional narrowing. MRI also allows an accurate assessment of the composition and size of atherosclerotic plaques, which permits assessment of the risk of plaque rupture and thrombus formation.

Aortic bodies

Aortic bodies develop progressively during fetal life. They attain maximum size in the first three postnatal years, when the largest are two brownish bodies, 1 cm long, which flank the abdominal aorta and are usually united anterior to it by a horizontal mass immediately above the inferior mesenteric artery, thereby forming an inverted
crescentic or H-shaped arrangement which is intimately related to the intermesenteric and superior hypogastric plexuses (see Fig. 15.16). Their constituent cells disperse and atrophy and by 14 years they may have disintegrated completely. When well developed, they consist of masses of polygonal chromaffin cells embedded in wide-meshed capillary plexuses and secreting noradrenaline (norepinephrine). Other small chromaffin bodies are also widespread in the fetus in the abdominal and pelvic prevertebral sympathetic plexuses. They reach a maximum size between the fifth and eighth fetal months, and survive in adults mainly near the coeliac and superior mesenteric arteries and as microscopic collections of cells that persist in the lower parts of the intermesenteric plexus.

Subclavian arteries

Right subclavian artery

The right subclavian artery arises from the brachiocephalic trunk. The right subclavian artery is formed behind the upper border of the right sternoclavicular joint. It ascends above the clavicle superomedial and then posterior to scalenus anterior. It next descends laterally to scalenus anterior, to the outer border of the first rib, where it becomes the axillary artery.

Left subclavian artery

In the majority of individuals, the left subclavian artery originates independently from the aortic arch after the origin of the brachiocephalic trunk and left common carotid artery. The left subclavian artery arises from the aortic arch below the left common carotid artery and rises into the neck lateral to the medial border of scalenus anterior, crosses behind this muscle and then descends towards the outer border of the first rib, where it becomes the axillary artery. A common origin exists occasionally between the left subclavian artery and left vertebral artery. Rarely, there are bilateral brachiocephalic trunks, which subsequently divide on both sides into common carotid and subclavian arteries.

Relations

In the thorax the left subclavian artery is related anteriorly to the left common carotid artery and left brachiocephalic vein, from which it is separated by the left vagus, cardiac and phrenic nerves. More superficially, the anterior pulmonary margin, pleura, sternothyroid and sternohyoid lie between the vessel and the upper left area of the manubrium of sternum. The left side of the oesophagus, the thoracic duct and longus colli are posterior. The left subclavian artery is in contact posterolaterally with the left lung and pleura. The trachea, the left recurrent laryngeal nerve, oesophagus and thoracic duct are medial. Laterally, the artery grooves the mediastinal surface of the left lung and pleura, which also encroach on its anterior and posterior aspects.

Common carotid arteries

The right and left carotid arteries differ in length and origin. The right carotid is exclusively cervical, and arises from the brachiocephalic trunk behind the right sternoclavicular joint. The left carotid originates directly from the aortic arch immediately posterolaterally to the brachiocephalic trunk and therefore has both thoracic and cervical parts.
**Right common carotid artery**

The right common carotid artery and its relations are described in Chapter 28.

**Left common carotid artery**

The left common carotid artery (see Fig. 28.14) ascends until level with the left sternoclavicular joint, where it enters the neck. It is 20–25 mm long and it lies at first in front of the trachea, then it inclines to the left. The further course of the artery is described in Chapter 28.

**Relations**

Sternohyoid and sternothyroid, the anterior parts of the left pleura and lung, the left brachiocephalic vein and the thymic remnants are anterior and separate the left common carotid artery from the manubrium. The trachea, left subclavian artery, left border of the oesophagus, left recurrent laryngeal nerve and thoracic duct are posterior. To the right are the brachiocephalic trunk (below) and the trachea, inferior thyroid veins and thymic remains (above). To the left are the left vagus and phrenic nerves, left pleura and lung.
VEINS

Superior vena cava

The superior vena cava returns blood to the heart from the tissues above the diaphragm. It is approximately 7 cm in length, and is formed by the junction of the brachiocephalic veins behind the lower border of the first right costal cartilage near the sternum. It descends vertically behind the first and second intercostal spaces, and ends in the upper right atrium behind the third right costal cartilage. Its inferior half is within the fibrous pericardium, which it pierces level with the second costal cartilage. Covered anterolaterally by serous pericardium (from which a retrocaval recess projects), it is slightly convex to the right (Figs 56.1, 56.3; see Fig. 28.14). The superior vena cava has no valves.

Relations

The anterior margins of the right lung and pleura are anterior and the pericardium intervenes below: these structures separate the superior vena cava from the internal thoracic artery, first and second intercostal spaces, and second and third costal cartilages. The trachea and right vagus are posteromedial, the right lung and pleura are posterolateral, and the right pulmonary hilum is posterior. The right phrenic nerve and pleura are right lateral and the brachiocephalic artery and ascending aorta are left lateral, the aorta overlapping the superior vena cava (see Fig. 58.3).

Variations

The brachiocephalic veins may enter the right atrium separately, the right vein descending like a normal superior vena cava. A left superior vena cava may have a slender connection with the right and then cross the left side of the aortic arch to pass anterior to the left pulmonary hilum before turning to enter the right atrium. It replaces the oblique atrial vein and coronary sinus and receives all the tributaries of the coronary sinus. The left brachiocephalic vein sometimes projects above the manubrium (more frequently in childhood), and crosses the suprasternal fossa in front of the trachea.

Tributaries

Tributaries of the superior vena cava are the azygos vein and small veins from the pericardium and other mediastinal structures (see Fig. 55.6).

Superior vena caval obstruction

Superior vena caval obstruction is characterized by headaches, facial congestion and facial oedema, reflecting impaired venous drainage of the head, neck and upper arms. It is often caused by bronchial carcinoma.
involving the right upper lobe of the lung, or by metastatic involvement of the right paratracheal lymph nodes resulting in circumferential narrowing or complete obstruction of the superior vena cava. This is usually considered to be an oncological emergency and symptoms may be relieved by insertion of a vascular stent or by radiotherapy to the affected region after a tissue diagnosis is established.

**Inferior vena cava**

The inferior vena cava returns blood to the heart from the tissues below the diaphragm. It passes through the diaphragm between the right leaf and central area of the central tendon of the diaphragm at the level of the eighth and ninth thoracic vertebrae, and drains into the inferoposterior part of the right atrium (see Fig. 58.1). The thoracic part is very short, and is partly inside and partly outside the pericardial sac. The extrapericardial part is separated from the right pleura and lung by the right phrenic nerve, and the intrapericardial part is covered, except posteriorly, by inflected serous pericardium. The abdominal course of the inferior vena cava is described in Chapter 62.

**Collateral venous channels**

In obstruction of the upper inferior vena cava, the azygos and hemiazygos veins and vertebral venous plexuses are the main collateral channels maintaining venous circulation. They connect the superior and inferior venae cavae and communicate with the common iliac vein by the ascending lumbar veins and with many tributaries of the inferior vena cava.

**Brachiocephalic veins**

The right and left brachiocephalic veins join to form the superior vena cava.

*Right brachiocephalic vein*

The right brachiocephalic vein is about 2.5 cm long, and begins posterior to the sternal end of the right clavicle. It descends almost vertically to join the left brachiocephalic vein, forming the superior vena cava posterior to the lower border of the first right costal cartilage, near the right sternal border. It is anterolateral to the brachiocephalic artery and right vagus nerve; the right pleura, phrenic nerve and internal thoracic artery are posterior to it above, and become lateral below (see Fig. 28.14). Its tributaries are the right vertebral, internal thoracic, inferior thyroid and sometimes the first right posterior intercostal veins.

*Left brachiocephalic vein*

The left brachiocephalic vein is longer than the right, being some 6 cm long.
It begins posterior to the sternal end of the left clavicle, anterior to the cervical pleura, and descends obliquely to the right, posterior to the upper half of the manubrium sterni, to the sternal end of the first right costal cartilage, where it joins the right brachiocephalic vein to form the superior vena cava. It is separated from the left sternoclavicular joint and manubrium by sternohyoid and sternothyroid, the thymus or its remains, and areolar tissue; terminally it is overlapped by the right pleura. It crosses anterior to the left internal thoracic, subclavian, brachiocephalic and common carotid arteries, left phrenic and vagus nerves, and the trachea. The aortic arch is inferior to it. Its tributaries are the left vertebral, internal thoracic, inferior thyroid, superior intercostal, sometimes the first left posterior intercostal, thymic and pericardial veins.
REFERENCES

CHAPTER 57 – Pleura, lungs, trachea and bronchi

The lungs are the essential organs of respiration and are responsible for the uptake of oxygen into the blood and the removal of carbon dioxide. The functional design of the thorax facilitates this complex process. The muscles of respiration and the diaphragm, acting together, increase the intrathoracic volume, creating a negative pressure within the pleural space which surrounds the lung and causing expansion of the lung (see Ch. 58). The resultant reduction in intra-alveolar pressure prompts the conduction of air through the upper respiratory tract into the trachea and airways and thence into the alveoli, where gaseous exchange occurs. The process of breathing exposes the lung to noxious agents, including gases, dust particles, bacteria and viruses; the mucous barrier, mucociliary escalator, branching pattern of the airways and the cough reflex are all anatomical defences against these insults. Anatomical defects may compromise respiratory function; for example, chest wall abnormalities may cause restrictive lung disease. Similarly, ultrastructural abnormalities such as ciliary dysfunction (as seen in Kartagener's syndrome) lead to recurrent respiratory infections and airway damage.

PLEURA

Each lung is covered by pleura, a serous membrane arranged as a closed invaginated sac. The visceral or pulmonary pleura adheres closely to the pulmonary surface and its interlobar fissures. Its continuation, the parietal pleura, lines the corresponding half of the thoracic wall and covers much of the diaphragm and structures occupying the middle region of the thorax. The visceral and parietal pleurae are continuous with each other around the hilar structures, and they remain in close, though sliding, contact at all phases of respiration. The potential space between them is the pleural cavity, which is maintained at a negative pressure by the inward elastic recoil of the lung and the outward pull of the chest wall.

The right and left pleural sacs form separate compartments and touch only behind the upper half of the sternal body (see Fig. 53.6A,B), although they are also close to each other behind the oesophagus at the midthoracic level. The region between them is the mediastinum (interpleural space). The left pleural cavity is the smaller of the two, because the heart extends further to the left. The upper and lower limits of the pleurae are about the same on the two sides, but the left sometimes descends lower in the midaxillary line.

The interlobar fissures and posterior azygo-oesophageal and retrosternal pleural reflections are the only aspects of the normal pleura that can be visualized on a chest radiograph or CT scan (Fig. 57.1A–D; see Figs 55.16, 55.17). Demonstration of significant pleural shadowing in any other regions usually implies pathological abnormalities of the pleura. Thoracoscopy allows the direct inspection of both the parietal and visceral surfaces. The parietal pleura is translucent and at thoracoscopy the underlying muscles and blood vessels are visible. The visceral pleura is also translucent and has a grey variegated appearance due to the underlying lung and the vascular network in the subpleural layer.
Fig. 57.1  A, Axial section through the lungs below the carina demonstrates the left and right major fissures. The circular avascular area anterior to the right major fissure and surrounded by a halo of white (arrow) is due to the horizontal (minor) fissure. In this subject the fissure is slightly domed and passing through the plane of the section. B, Axial section through the lungs at the mid left atrial level demonstrating the left and right major fissures as they pass more anteriorly and separate the lower lobes from the lingula and middle lobes. C, Sagittal section through the right lung demonstrating the major and minor fissures (arrows). D, Sagittal section through the left lung demonstrating the major fissure (arrow).

**PARIETAL PLEURA**

Different regions of parietal pleura are customarily distinguished by name, thus the costovertebral pleura lines the internal surface of the thoracic wall and the vertebral bodies, the diaphragmatic pleura lies on the thoracic surface of the diaphragm, the cervical pleura lies over the pulmonary apices (and is therefore also called the dome of the pleura), and the mediastinal pleura is applied to the structures between the lungs.

**Costovertebral pleura**

Costovertebral pleura lines the sternum, ribs, transversus thoracis and intercostal muscles and the sides of the vertebral bodies; normally it is easily separated from these structures. External to the pleura is a thin layer of loose connective tissue, the endothoracic fascia, which corresponds to the transversalis fascia of the abdominal wall. Anteriorly, the costal pleura begins behind the sternum, where it is continuous with the mediastinal pleura along a junction extending from behind the sternoclavicular joint down and medially to the midline behind the sternal angle. From here, the right and left costal pleurae descend in contact with each other to the level of the fourth costal cartilages and then diverge. On the right side, the line descends to the back of the xiphisternal joint, while on the left the line diverges laterally and
descends at a distance of 2–2.5 mm from the sternal margin to the sixth costal cartilage, forming the cardiac notch. On each side, the costal pleura sweeps laterally, lining the internal surfaces of the costal cartilages, ribs, transversus thoracis and intercostal muscles. Posteriorly, it passes over the sympathetic trunk and its branches to reach the sides of the vertebral bodies, where it is again continuous with the mediastinal pleura. The costovertebral pleura is continuous with the cervical pleura at the inner margin of the first rib and below it becomes continuous with the diaphragmatic pleura along a line which differs slightly on the two sides. On the right, this line of costodiaphragmatic reflection begins behind the xiphoid process, passes behind the seventh costal cartilage to reach the eighth rib in the midclavicular line, the tenth rib in the midaxillary line, and then ascends slightly to cross the twelfth rib level with the upper border of the twelfth thoracic spine (see Fig. 53.6A,B). On the left, the line initially follows the ascending part of the sixth costal cartilage, but then follows a course similar to that on the right, although it may be slightly lower.

Diaphragmatic pleura

The diaphragmatic pleura is a thin, tightly adherent layer which covers most of the upper surface of the diaphragm. It is continuous with the costal pleura and on its medial aspect is continuous with the mediastinal pleura along the line of attachment of the pericardium to the diaphragm.

Cervical pleura

The cervical pleura is a continuation of the costovertebral pleura over the pulmonary apex (Fig. 57.2). It ascends medially from the internal border of the first rib to the apex of the lung, as high as the lower edge of the neck of the first rib, and then descends lateral to the trachea to become the mediastinal pleura. As a result of the obliquity of the first rib, the cervical pleura extends 3–4 cm above the first costal cartilage, but not above the neck of the first rib. The cervical pleura is strengthened by a fascial suprapleural membrane, which is attached in front to the internal border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. It contains a few muscular fibres, which spread from the scaleni. Scalenus minimus extends from the anterior border of the transverse process of the seventh cervical vertebra to the inner border of the first rib behind its subclavian groove, and also spreads into the pleural dome, which it therefore tenses: it has been suggested that the suprapleural membrane is the tendon of scalenus medius. The cervical pleura (like the pulmonary apex) reaches the level of the seventh cervical spine approximately 2.5 cm from the midline. Its projection is a curved line from the sternoclavicular joint to the junction of the medial and middle thirds of the clavicle, its summit being 2.5 cm above it. The subclavian artery ascends laterally in a furrow below the summit of the cervical pleura (Fig. 57.2).
Mediastinal pleura

The mediastinal pleura is the lateral boundary of the mediastinum and forms a continuous surface above the hilum of the lung from sternum to vertebral column. On the right it covers the right brachiocephalic vein, the upper part of the superior vena cava, the terminal part of the azygos vein, the right phrenic and vagus nerves, the trachea and oesophagus. On the left it covers the aortic arch, left phrenic and vagus nerves, left brachiocephalic and superior intercostal veins, left common carotid and subclavian arteries, thoracic duct and oesophagus. At the hilum of the lung it turns laterally to form a tube that encloses the hilar structures and is continuous with the pulmonary pleura.
VISCERAL PLEURA

The pulmonary pleura is inseparably adherent to the lung over all its surfaces, including those in the fissures, except at the root or hilum of the lung and along a line descending from this, which marks the attachment of the pulmonary ligament (Figs 57.3, 57.4).

Fig. 57.3 The right lung. A, Lateral surface. B, Medial surface. (From Sobotta 2006.)
Fig. 57.4 The left lung. A, Lateral surface. B, Medial surface.
(From Sobotta 2006.)
INFERIOR PULMONARY LIGAMENTS

Below the hilum the mediastinal pleura extends as a double layer, the pulmonary ligament, from the lateral surface of the oesophagus to the mediastinal surface of the lung, where it is continuous with the parietal pleura (Figs 57.3, 57.4). It is continuous above with the pleura around the hilar structures and below it ends in a free sickle-shaped border.
PLEURAL RECESSES

The pleura extends considerably beyond the inferior border of the lung, but not as far as the attachment of the diaphragm, which means that the diaphragm is in contact with the costal cartilages and intercostal muscles below the line of pleural reflection from the thoracic wall to the diaphragm. In quiet inspiration the inferior margin of the lung does not reach this reflection, and the costal and diaphragmatic pleurae are separated merely by a narrow slit, the costodiaphragmatic recess. In quiet inspiration the lower limit of the lung is normally 5 cm above the lower pleural limit. A similar costomediastinal recess exists behind the sternum and the costal cartilages, where the thin anterior margin of the lung falls short of the line of pleural reflection. The extent of this recess, the anterior costomediastinal line of pleural reflection, and the position of the anterior margin of the lung all exhibit individual variation.

The inferior border of the right costodiaphragmatic recess is an important consideration in the surgical posterior approach to the kidney. Usually the pleura crosses the twelfth rib at the lateral border of erector spinae, so that the medial region of the kidney is above the pleural reflection (see Fig. 53.6B). However, if the twelfth rib does not project beyond the muscle, the eleventh rib may be mistaken for the twelfth in palpation, and an incision prolonged to this level will damage the pleura. Whether the lowest palpable rib is the eleventh or twelfth can be ascertained by counting from the second rib (identified at its junction with the sternal angle).
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The parietal and visceral pleurae are developed from somatopleural and splanchnopleural layers of the lateral plate mesoderm respectively, which means that the parietal pleura is supplied by arteries from somatic sources. The costovertebral pleura is supplied by branches of intercostal and internal thoracic arteries; the mediastinal pleura is supplied by branches from bronchial, upper diaphragmatic, internal thoracic and mediastinal arteries; the cervical pleura is supplied by branches from the subclavian artery; and the diaphragmatic pleura is supplied by the superficial part of the microcirculation of the diaphragmatic muscle. The veins join systemic veins in the thoracic wall which drain into the superior vena cava. Lymph from the costovertebral parietal pleura drains into the internal thoracic chain anteriorly and intercostal chains posteriorly, while that from the diaphragmatic pleura drains into the mediastinal, retrosternal and coeliac axis nodes.

The visceral pleura forms an integral part of the lung and accordingly its arterial supply and venous drainage are provided by the bronchial vessels. The bronchial arteries at the hilum form an anulus that surrounds the main bronchus, and pleural branches from this anulus supply the visceral pleura facing the mediastinum, interlobar surfaces, apical surface and part of the diaphragmatic surface. The visceral pleura is drained by pulmonary veins, apart from an area around the hilum that drains into bronchial veins. The lymphatic drainage of the visceral pleura is to the deep pulmonary plexus within the interlobar and peribronchial spaces.
INNERVATION

The costal and peripheral diaphragmatic parietal pleurae are innervated by intercostal nerves, and the mediastinal and central diaphragmatic parietal pleurae are innervated by the phrenic nerve. Irritation of the former results in pain that is referred along the intercostal nerves to the appropriate part of the thoracic or abdominal wall, whereas irritation of the central diaphragmatic pleura causes pain that is referred to the lower neck and shoulder tip, i.e. to the C3, 4 dermatomes. The visceral pleura is innervated by visceral afferents that reach it by travelling along the bronchial vessels with the autonomic fibres.
PNEUMOTHORAX

Any breach of the chest wall and parietal pleura or visceral pleura leads to the accumulation of air within the pleural cavity (pneumothorax). Fluid (hydrothorax), blood (haemothorax) and rarely lymph (chylothorax) can also accumulate in this space. Pneumothoraces may occur spontaneously or following trauma (e.g. rib fractures, penetrating injuries from sharp instruments, iatrogenic injury). Significant air in the pleural space is visible on a chest radiograph: there is separation of the parietal and visceral pleurae and an absence of pulmonary vascular markings in the corresponding area. Occasionally, a ball valve-like effect occurs, so that air enters the pleural space during inspiration but cannot escape in expiration. This tension pneumothorax can be life-threatening and should be suspected whenever there are unilateral decreased breath sounds and hyperresonance on percussion, hypotension, jugular venous distension and contralateral tracheal deviation. A tension pneumothorax requires immediate decompression by the insertion of an intercostal drain or wide bore catheter. Fluid collection in the pleural space may be due to congestive cardiac failure, hypoalbuminaemia, inflammatory, infective or neoplastic conditions. A pleural effusion causes obliteration of the costophrenic angle and the diaphragm, and a lateral meniscus is visible on a frontal chest radiograph. Drainage of the fluid and subsequent analysis is required for diagnostic purposes. Where there is a collection of pus (empyema) or blood, pleural drainage is essential for therapeutic purposes. Ultrasonography is useful in assessing the size and characteristics of an effusion, such as the presence of loculation and debris. It may even demonstrate underlying consolidated lung. Computed tomography is utilized to assess the underlying hidden lung parenchyma and mediastinal glands. For further review of the radiology of the pleurae and lungs, see Armstrong (2000).
MICROSTRUCTURE

The pleural surface is smooth and moistened by serous fluid. It consists of a single layer of flat mesothelial cells separated by a basal lamina from an underlying lamina propria of loose connective tissue. Ultrastructurally, pleural mesothelial cells are like those of the peritoneum in that they have highly folded basal plasma membranes, their adjacent cell surfaces interdigitate and are joined by desmosomes, and their luminal surfaces bear numerous microvilli and some cilia. Pinocytotic vesicles are common in their cytoplasm.

The deeper layers of the lamina propria are continuous with the tissue surrounding the pulmonary lobules. Blood and lymph vessels and nerves all travel within the pleura.

Serosa

The serosa is formed by the visceral pleura, which is a transparent single sheet of mesothelium covering a thin lamina propria of connective tissue, and is closely attached to the various structures of the lung, except at the hilum. Beneath the serosa, loose connective tissue covers the entire pulmonary surface: it extends from the hilum along the conducting tubes and blood vessels within the substance of the lung. The connective tissue partitions the lung into numerous lobules, small polyhedral tissue masses which each receives a lobular bronchiole and the terminal branches of arterioles, venules, lymphatics and nerves. Lobules vary in size, the superficial ones are the largest, and are visible as polygonal areas 5–15 mm across.
LUNGS

The lungs are the essential organs of respiration. They are situated on either side of the heart and other mediastinal contents (Figs 57.3, 57.4). Each lung is free in its pleural cavity, except for its attachment to the heart and trachea at the hilum and pulmonary ligament respectively. When removed from the thorax, a fresh lung is spongy, can float in water, and crepitates when handled, because of the air within its alveoli. It is also highly elastic and so it retracts on removal from the thorax. Its surface is smooth and shiny and is separated by fine, dark lines into numerous small polyhedral domains, each crossed by numerous finer lines, indicating the areas of contact between its most peripheral lobules and the pleural surface.

At birth the lungs are pink, but in adults they are dark grey and patchily mottled. As age advances, this maculation becomes black, as granules of inhaled carbonaceous material are deposited in the loose connective tissue near the lung surface. Darkening is often more marked in men than women, in those who have dwelt in industrial areas and in smokers. The posterior pulmonary border is usually darker than the anterior. In the upper, less movable parts of the lung, this surface pigmentation tends to be concentrated opposite the intercostal spaces. Lungs from fetuses or stillborn infants who have not respired differ from those of infants who have taken a breath in that they are firm, non-crepitant and do not float in water.

The adult right lung usually weighs 625 g, and the left 565 g, but the range of wet weights is considerable, not least because it reflects the amount of blood or serous fluid contained within the lungs when weighed. In proportion to body stature, the lungs are heavier in men than in women.

PULMONARY SURFACE FEATURES

Each lung has an apex, base, three borders and two surfaces (Figs 57.3, 57.4). In shape, each lung approximates to half a cone.

Apex

The apex, the rounded upper extremity, protrudes above the thoracic inlet where it contacts the cervical pleura, and is covered in turn by the suprapleural membrane. As a consequence of the obliquity of the inlet, the apex rises 3–4 cm above the level of the first costal cartilage; it is level posteriorly with the neck of the first rib. Its summit is 2.5 cm above the medial third of the clavicle. The apex is therefore in the root of the neck (see Fig. 35.5A). It has been claimed that, because the apex does not rise above the neck of the first rib, it is really intrathoracic, and that it is the anterior surface that ascends highest in inspiration. The subclavian artery arches up and laterally over the suprapleural membrane, grooves the anterior surface of the
apex near its summit and separates it from scalenus anterior. The cervicothoracic (stellate) sympathetic ganglion, the ventral ramus of the first thoracic spinal nerve and the superior intercostal artery all lie posterior to the apex. Scalenus medius is lateral, the brachiocephalic artery, right brachiocephalic vein and trachea are adjacent to the right medial surface of the lung, and the left subclavian artery and left brachiocephalic vein are adjacent to the left medial surface of the apex of the lung.

Base

The basal surface is semilunar and concave, and rests upon the superior surface of the diaphragm, which separates the right lung from the right lobe of the liver and the left lung from the left lobe of the liver, the gastric fundus and spleen. Since the diaphragm extends higher on the right than on the left, the concavity is deeper on the base of the right lung. Posterolaterally, the base has a sharp margin that projects a little into the costodiaphragmatic recess.

Costal surface

The costal surface of the lung is smooth and convex, and its shape is adapted to that of the thoracic wall, which is vertically deeper posteriorly. It is in contact with the costal pleura; in specimens that have been preserved in situ, this surface exhibits grooves that correspond with the overlying ribs.

Medial surface

The medial surface has a posterior vertebral and anterior mediastinal part. The vertebral part lies in contact with the sides of the thoracic vertebrae and intervertebral discs, the posterior intercostal vessels and the splanchnic nerves. The mediastinal area is deeply concave, because it is adapted to the heart at the cardiac impression, which is much larger and deeper on the left lung where the heart projects more to the left of the median plane. Posterosuperior to this concavity is the somewhat triangular hilum, where various structures enter or leave the lung, collectively surrounded by a sleeve of pleura that also extends below the hilum and behind the cardiac impression as the pulmonary ligament.

Other impressions on the lung surface

In addition to these pulmonary features, cadaveric lungs that have been preserved in situ can show a number of other impressions that indicate their relations with surrounding structures (Figs 57.3, 57.4). On the right lung the cardiac impression is related to the anterior surface of the right auricle, the anterolateral surface of the right atrium and partially to the anterior surface of the right ventricle. The impression ascends anterior to the hilum as a wide groove for the superior vena cava and the terminal portion of the right
brachiocephalic vein. Posteriorly this groove is joined by a deep sulcus which arches forwards above the hilum and is occupied by the azygos vein. The right side of the oesophagus makes a shallow vertical groove behind the hilum and the pulmonary ligament. Towards the diaphragm it inclines left and leaves the right lung, and therefore does not reach the lower limit of this surface. Posteroinferiorly the cardiac impression is confluent with a short wide groove adapted to the inferior vena cava. Between the apex and the groove for the azygos, the trachea and right vagus are close to the lung, but do not mark it.

On the left lung (Fig. 57.4) the cardiac impression is related to the anterior and lateral surfaces of the left ventricle and auricle. The anterior infundibular surface and adjoining part of the right ventricle is also related to the lung as it ascends in front of the hilum to accommodate the pulmonary trunk. A large groove arches over the hilum, and descends behind it and the pulmonary ligament, corresponding to the aortic arch and descending aorta. From its summit a narrower groove ascends to the apex for the left subclavian artery. Behind this, above the aortic groove, the lung is in contact with the thoracic duct and oesophagus. In front of the subclavian groove there is a faint linear depression for the left brachiocephalic vein. Inferiorly, the oesophagus may mould the surface in front of the lower end of the pulmonary ligament.

**Pulmonary borders**

The inferior border is thin and sharp where it separates the base from the costal surface and extends into the costodiaphragmatic recess, and is more rounded medially where it divides the base from the mediastinal surface. It corresponds, in quiet respiration, to a line drawn from the lowest point of the anterior border which passes to the sixth rib at about the midclavicular line, then to the eighth rib in the midaxillary line (usually 10 cm above the costal margin), and then continues posteriorly, medially and slightly upwards to a point 2 cm lateral to the tenth thoracic spine (see Fig. 53.5A,B). The diaphragm rises higher on the right to accommodate the liver, and so the right lung is vertically shorter (by approximately 2.5 cm) than the left. However, cardiac asymmetry means that the right lung is broader, and has a greater capacity and weight than the left. The posterior border separates the costal surface from the mediastinal surface, and corresponds to the heads of the ribs. It has no recognizable markings and is really a rounded junction of costal and vertebral (medial) surfaces. The thin, sharp, anterior border overlaps the pericardium. On the right it corresponds closely to the costomediastinal line of pleural reflection, and is almost vertical. On the left it approaches the same line above the fourth costal cartilage; below this point it shows a variable cardiac notch, the edge of which passes laterally for 3.5 cm before curving down and medially to the sixth costal cartilage 4 cm from the midline. It therefore does not reach the line of pleural reflection here (see Fig. 53.5A) and so the pericardium is covered only by a double layer of pleura.
(area of superficial cardiac dullness). However, surgical experience suggests that the line of pleural reflection, the anterior pulmonary margin and the costomedial pleural recess are all variable.
PULMONARY FISSURES AND LOBES

Right lung

The right lung is divided into superior, middle and inferior lobes by an oblique and a horizontal fissure (Fig. 57.3). The upper, oblique fissure separates the inferior from the middle and upper lobes, and corresponds closely to the left oblique fissure, although it is less vertical, and crosses the inferior border of the lung approximately 7.5 cm behind its anterior end. On the posterior border it is either level with the spine of the fourth thoracic vertebra or slightly lower. It descends across the fifth intercostal space and follows the sixth rib to the sixth costochondral junction. The short horizontal fissure separates the superior and middle lobes. It passes from the oblique fissure, near the midaxillary line, horizontally forwards to the anterior border of the lung, level with the sternal end of the fourth costal cartilage, then passes backwards to the hilum on the mediastinal surface. The horizontal fissure is usually visible on a frontal chest radiograph. The oblique fissure is usually visible on a lateral radiograph and on a high resolution CT scan as a curvilinear band from the lateral aspect to the hilum (Fig. 57.1A–D). The small middle lobe is cuneiform and includes some of the costal surface, the lower part of the anterior border and the anterior part of the base of the lung. Sometimes the medial part of the upper lobe is partially separated by a fissure of variable depth which contains the terminal part of the azygos vein, enclosed in the free margin of a mesentery derived from the mediastinal pleura, and forming the ‘lobe of the azygos vein’. This varies in size, and sometimes includes the apex of the lung. It is always supplied by one or more branches of the apical bronchus. Radiographically, a pleural effusion may be limited to the azygos fissure. Less common variations are the presence of an inferior accessory fissure, which separates the medial basal segment from the remainder of the lower lobe, and a superior accessory fissure, which separates the apical segment of the lower lobe from the basal segments. The identification of the completeness of the fissures is important prior to lobectomy, because individuals with incomplete fissures are more prone to develop postoperative air leaks, and may require further procedures such as stapling and pericardial sleeves (see Venuta et al 1998).

Left lung

The left lung is divided into a superior and an inferior lobe by an oblique fissure (Fig. 57.4) which extends from the costal to the medial surfaces of the lung both above and below the hilum. Superficially this fissure begins on the medial surface at the posterosuperior part of the hilum. It ascends obliquely backwards to cross the posterior border of the lung 6 cm below the apex, then descends forwards across the costal surface, to reach the lower border almost at its anterior end. It finally ascends on the medial surface to the lower part of the hilum. At the posterior border of the lung the fissure usually lies opposite a surface point 2 cm lateral to the midline between the spines of the third and fourth thoracic vertebrae, but it may be above or below this level. Traced around the chest, the fissure reaches the fifth intercostal space (at or near the midaxillary line) and follows this to intersect the inferior border of the lung close to, or just below, the sixth costochondral junction (7.5 cm from the midline). The left oblique fissure is usually more vertical than the right, and is indicated approximately by the medial border of the scapula when the arm is fully abducted above the shoulder. A left horizontal fissure is a normal variant found occasionally.
The superior lobe, which lies anterosuperior to the oblique fissure, includes the apex, anterior border, much of the costal and most of the medial surfaces of the lung. At the lower end of the cardiac notch a small process, the lingula, is usually present. The larger inferior lobe lies behind and below the fissure, and contributes almost the whole of the base, much of the costal surface and most of the posterior border of the lung.

**Bronchopulmonary segments**

Each of the principal bronchi divides into lobar bronchi. Primary branches of the right and left lobar bronchi are termed segmental bronchi because each ramifies in a structurally separate, functionally independent, unit of lung tissue called a bronchopulmonary segment (Figs 57.5–57.7).
Fig. 57.5 Lungs and bronchi, ventral aspect. The lobar and segmental bronchi are projected onto the lung in different colours (compare with Fig. 57.6).

(From Sobotta 2006.)
Fig. 57.6 Bronchopulmonary segments of the right and left lungs, coloured to indicate the different territories. A, Right lung, lateral aspect. B, Left lung, lateral aspect. C, Right lung, medial aspect. D, Left lung, medial aspect. Generally, this segment is not a separate unit, but is fused with the anterior basal segment. (From Sobotta 2006.)
The main segments are named and numbered as follows:

<table>
<thead>
<tr>
<th><strong>Right lung</strong></th>
<th></th>

</tr>
</tbody>
</table>

Each segment is surrounded by connective tissue that is continuous with the visceral pleura, and is a separate respiratory unit. The vascular and lymphatic arrangements of the segments are described on pages 996–998.
**PULMONARY HILA**

The pulmonary root connects the medial surface of the lung to the heart and trachea and is formed by a group of structures which enter or leave the hilum (Figs 57.3, 57.4; see also Fig. 55.4B). These are the principal bronchus, pulmonary artery, two pulmonary veins, bronchial vessels, a pulmonary autonomic plexus, lymph vessels, bronchopulmonary lymph nodes and loose connective tissue, all of which are enveloped by a sleeve of pleura. The pulmonary roots, or pedicles, lie opposite the bodies of the fifth to seventh thoracic vertebrae. The phrenic nerve, pericardiacophrenic artery and vein, and anterior pulmonary plexus are common anterior relations of both hila, and the vagus nerve and posterior pulmonary plexus are common posterior relations. The pulmonary ligament is a common inferior relation. The major structures in both roots are similarly arranged, so that the upper of the two pulmonary veins is anterior, the pulmonary artery and principal bronchus are more posterior, and the bronchial vessels are most posterior. The arrangement of bronchopulmonary segments and the pulmonary hila permit the resection of abscesses and localized lesions caused by lung cancer.

**Right hilum**

The right root is situated behind the superior vena cava and right atrium and below the terminal part of the azygos vein. The usual sequence of hilar structures from above downwards is: superior lobar bronchus, pulmonary artery, principal bronchus, and lower pulmonary vein (Fig. 57.3).

**Left hilum**

The left root lies below the aortic arch and in front of the descending thoracic aorta. The usual vertical sequence of structures at the left hilum is pulmonary artery, principal bronchus, and lower pulmonary vein (Fig. 57.4). The pulmonary artery is longer on the left side, and each of its branches from the hilum to the oblique fissure must be identified in pulmonary resections.
SECONDARY PULMONARY LOBULES

Each segmental bronchus supplies a bronchopulmonary segment. Progressive subdivisions of the bronchus occur within each segment and the bronchi become increasingly narrow. All intrapulmonary bronchi are kept patent by cartilaginous plates, which decline in size and number and finally disappear when the tubes are less than 1 mm in diameter (bronchioles). The terminal bronchiole is the most peripheral bronchiole not to have alveoli in its wall. Distal to each terminal bronchiole is an acinus, which consists of three to four orders of respiratory bronchioles, leading to three to eight orders of alveolar ducts. The walls of these ducts consist of alveolar sacs or the mouths of alveoli. The primary lobule is the lung distal to the respiratory bronchiole. The secondary lobule is the smallest subsection of the peripheral lung bounded by connective tissue septa and consists of approximately six terminal bronchioles. The connective tissue septa are uneven in both size and shape.
The lungs have two functionally distinct circulatory pathways. The pulmonary vessels convey deoxygenated blood to the alveolar walls and drain oxygenated blood back to the left side of the heart, and the much smaller bronchial vessels, which are derived from the systemic circulation, provide oxygenated blood to lung tissues that do not have close access to atmospheric oxygen, i.e. those of the bronchi and larger bronchioles.

The pulmonary artery bifurcates into right and left pulmonary arteries which pass to the hila of the lungs. On entering the lung tissue, both arteries divide into branches that accompany segmental and subsegmental bronchi and lie mostly dorsolateral to them. The pulmonary capillaries form plexuses immediately outside the epithelium in the walls and septa of alveoli and alveolar sacs. The plexus forms a single layer in the interalveolar septa, with meshes smaller than the capillaries, and exceedingly thin walls. Pulmonary veins, two from each lung, drain the pulmonary capillaries. Their radicles coalesce into larger branches which traverse the lung independently of the pulmonary arteries and bronchi. Communicating freely, they form large vessels that ultimately accompany the arteries and bronchial tubes to the pulmonary hilum, where the bronchi often separate the dorsolateral artery and the ventromedial vein. The pulmonary veins open into the left atrium and convey oxygenated blood for systemic distribution by the left ventricle.

At the hilum, the pulmonary vessels accompany the main bronchial divisions. This is not the case in the bronchopulmonary segments, where a segmental bronchus, its branches and associated arteries occupy a central position in each segment, but the many tributaries of the pulmonary veins run between segments, serving adjacent segments (which therefore drain into more than one vein). Some veins also lie beneath the visceral pleura, including the pleura in the interlobar fissures. It follows from this that a bronchopulmonary segment is not a complete vascular unit with an individual bronchus, artery and vein. During resection of segments, it is obvious that the planes between them are not avascular but are crossed by pulmonary veins and sometimes by branches of arteries. This pattern of bronchi, arteries and veins exhibits considerable variation: veins are the most variable, and arteries are more variable than bronchi.

**Pulmonary arteries**

The right pulmonary artery divides into two large branches as it emerges behind the superior vena cava (Fig. 57.8). A lymph node usually occupies the bifurcation. The superior branch, which is the smaller of the two, goes to the superior lobe and usually divides into two further branches, which supply the majority of that lobe. The inferior branch descends anterior to the intermediate bronchus and immediately posterior to the superior pulmonary
vein. It provides a small recurrent branch to the superior lobe, then at the point where the horizontal fissure meets the oblique fissure, it gives off the branch to the middle lobe anteriorly, and the branch to the superior segment of the inferior lobe posteriorly. It then continues a short distance before dividing to supply the rest of the inferior lobe segments.

Fig. 57.8 The relationship between the central airways and the pulmonary vessels. The numbers in the lower figure denote the numbers of the bronchopulmonary segments.

The left pulmonary artery emerges from within the concavity of the aortic arch
and descends anterior to the descending aorta to enter the oblique fissure (Fig. 57.8). The branches of the left pulmonary artery are extremely variable. The first and largest branch is usually given off to the anterior segment of the left superior lobe. Before reaching the oblique fissure, the artery gives off a variable number of other branches to the superior lobe, and as it enters the fissure it usually supplies a large branch to the superior segment of the inferior lobe. Lingular branches arise within the fissure, and the rest of the lower lobe is supplied by many varied branching patterns: it was a surgical aphorism of the late Lord Brock that when performing a left upper lobectomy, … ‘there was always one more branch of the pulmonary artery than you thought!’.

**Pulmonary sequestration**

When a portion of lung exists without the appropriate bronchovascular connections, it is usually supplied by the systemic vasculature. Extralobar pulmonary sequestration segments are covered by visceral pleura and usually found below the left lower lobe, whereas intralobar abnormalities are usually embedded in normal lung, classically the posterior basal segment of the left lower lobe. Extralobar pulmonary sequestration *per se* is asymptomatic, but is often associated with other congenital abnormalities.

**Pulmonary arteriography and embolization**

A thrombus that forms in the legs or pelvic veins may embolize and travel in the right side of the circulation through the right atrium and right ventricle and then lodge in the pulmonary vasculature. The clinical abnormalities observed depend on the size of the embolus. Large emboli may lodge in the main pulmonary artery branches and cause right ventricular dysfunction and hypoxia. Smaller emboli may lodge in segmental pulmonary arteries and cause pleuritic chest pain, shortness of breath and haemoptysis. Pulmonary emboli cause a ventilation/perfusion mismatch that can have serious physiological implications leading to a significant reduction in the oxygenation of blood. Ventilation/perfusion scans with radiolabelled xenon and technetium usually demonstrate segmental abnormalities in perfusion with normal ventilation in the corresponding regions. Pulmonary emboli may also be evaluated by contrast-enhanced spiral CT or pulmonary angiograms and appear as filling defects.

**Pulmonary veins**

There are usually four pulmonary veins, two from each lung. They originate from capillary networks in the alveolar walls and return oxygenated blood to the left atrium. All the main tributaries of the pulmonary veins receive smaller tributaries, both intra- and inter-segmental; by repeated junctions, tributary veins finally form a single trunk in each lobe, i.e. three in the right lung, and
two in the left. The right middle and superior lobar veins usually join and so two veins, superior and inferior, leave each lung.

In the pulmonary hilum, the usual distribution of veins is as follows. The superior pulmonary vein is anteroinferior to the pulmonary artery, and the inferior is the most inferior hilar structure and also slightly posterior. On the right, the union of apical, anterior and posterior veins (draining the upper lobe) with a middle lobar vein (formed by lateral and medial tributaries; Fig. 57.8) forms the superior right pulmonary vein. The inferior right pulmonary vein is formed by the hilar union of superior (apical) and common basal veins from the lower lobe. The union of superior and inferior basal tributaries forms the common basal vein. Occasionally the three right lobar veins remain separate. The right superior pulmonary vein passes posterior to the superior vena cava, the inferior behind the right atrium. On the left, the superior left pulmonary vein, which drains the upper lobe, is formed by the union of apicoposterior (draining the apical and posterior segments), anterior and lingular veins (Fig. 57.8). The inferior left pulmonary vein, which drains the lower lobe, is formed by the hilar union of two veins, superior (apical) and common basal, the latter formed by the union of a superior and an inferior basal vein. Both superior and inferior left pulmonary veins pass anterior to the descending thoracic aorta. Sometimes the two left pulmonary veins form a single trunk, or they may be augmented by an accessory lobar vein from each lobe, which unite to form a third left pulmonary vein.

The right and left pulmonary veins perforate the fibrous pericardium and open separately in the posterosuperior aspect of the left atrium (see Figs 56.1, 56.2B). Their terminations are separated centrally by the oblique pericardial sinus, and laterally by smaller and variable pulmonary venous pericardial recesses that are directed medially and upwards. The pulmonary veins are devoid of valves.

**Lymphatics**

Pulmonary lymphatic vessels originate in a superficial subpleural plexus. A deep plexus accompanies the branches of the pulmonary vessels and bronchi. Superficial efferents turn round lung borders and the margins of fissures to converge in the bronchopulmonary nodes. There is little anastomosis between the superficial and deep lymphatics, except in the hilar regions. In peripheral parts of the lungs, small channels connect superficial and deep lymphatic vessels, and are capable of dilatation to direct lymph from the deep to the superficial channels when outflow from deep vessels is obstructed by pulmonary disease. There is a tendency for vessels from the upper lobes to pass to the superior tracheobronchial nodes, and those from lower lobes to the inferior tracheobronchial group; however, lymphatic vessels of adjoining lobes connect deep in the fissures and so these connections are not exclusive. At the level of pulmonary lobation, the
arrangement of lymphatic vessels follows the central artery of a lobule and its peripheral veins. Lymphoid aggregations, non-follicular in appearance, occur in peribronchial sites and in 'placoid' formations adjoining pulmonary pleura.
INNERVATION

The autonomic nervous system controls many aspects of airway function, including regulation of airway smooth muscle tone, mucus secretion from submucosal glands and surface epithelial goblet cells, vascular permeability and blood flow (see Belvisi 2002).

Pulmonary plexuses

The pulmonary plexuses lie anterior and posterior to the other hilar structures of the lungs (see Fig. 56.20). The anterior plexus is small and is formed by rami from vagal and sympathetic cervical cardiac nerves via connections with the superficial cardiac plexus. The posterior pulmonary plexus is formed by the rami of vagal and sympathetic cardiac branches from the second to fifth or sixth thoracic sympathetic ganglia. The left plexus also receives branches from the left recurrent laryngeal nerve. Further details of the pulmonary plexuses are given in the description of the cardiac plexuses in Chapter 56.
MICROSTRUCTURE OF RESPIRATORY SURFACES

Thin-walled respiratory surfaces (alveoli) are distributed as isolated patches within the walls of respiratory bronchioles, and as tube-like alveolar ducts and balloon-like alveolar sacs which contain groups of adjacent alveoli.

Alveolar area

Normal adult human alveoli have a mean total surface area of 143 m$^2$: an adult respiratory system contains of the order of 300 million alveoli. Their inflated diameter varies with lung position, and is greater in the upper regions than in the lower, because of the increased gravitational pressure at the lung base. These values vary considerably between normal young individuals; the differences become even more marked with age as a consequence of degenerative changes.

Alveolar structure

The alveoli are thin-walled pouches which provide the respiratory surface for gaseous exchange (Figs 57.9–57.11). Their walls contain two types of epithelial cell (pneumocytes) and cover a delicate connective tissue within which a network of capillaries ramifies. Since the walls are extremely thin, they present a minimal barrier to gaseous exchange between the atmosphere and the blood in the capillaries. Adjacent alveoli are frequently in close contact and then the intervening connective tissue forms the central part of an interalveolar septum. Alveolar macrophages are present within the alveolar lumen, and migrate over the epithelial surface.
Fig. 57.9 The respiratory tree and its blood supply and drainage, lymphatic drainage and nerve supply. The distribution of the different epithelial cells is shown. Blue = vessels which contain deoxygenated blood; red = vessels which contain oxygenated blood.
Fig. 57.10 The respiratory portion of the lung and its cell types.
Interalveolar septum

The alveolar lining epithelium varies in thickness, but extensive areas of it are as little as 0.05 µm thick (see Fig. 57.11). The epithelium lies on a basal lamina, which, in the thin portions of a septum, is fused with the basal lamina surrounding the adjacent capillaries. The total barrier to diffusion between air and blood in these thin portions may be as little as 0.2 µm. The thick portions of a septum contain connective tissue elements, including elastic fibres, collagen type III fibres, resident and migratory cells (Fig. 57.10).

Alveolar epithelial cells (pneumocytes)

The alveolar epithelium is a mosaic of types I and II pneumocytes. Type I pneumocytes are simple squamous epithelial cells and form over 90% of the alveolar area. Their basal laminae fuse with the basal laminae of the adjacent capillary endothelium to form the thin portions of interalveolar septa. Their cytoplasm is thin (0.05–0.2 µm) which facilitates gaseous diffusion between the lumen of the alveolus and its capillaries. The edges of adjacent cells overlap; they are joined by tight junctions, creating a strict diffusion barrier between the alveolar surface and underlying tissues. Together with a similar endothelial barrier, this arrangement limits the movement of fluid from blood and interstitial spaces into the alveolar lumen (the blood–air barrier). If damaged, type I cells, which do not divide, are replaced by type II cells, which proliferate and differentiate into type I pneumocytes.

The smaller type II cells are often more numerous than type I cells, but they contribute less than 10% of the alveolar surface area. They are rounded cells and protrude from
the alveolar surface, particularly at the angles between alveolar profiles. In the human lung they are often associated with interalveolar pores of Kohn. Their cytoplasm contains numerous characteristic secretory lamellar bodies consisting of concentric whorls of phospholipid-rich membrane, the precursors of alveolar surfactant (Fig. 57.11C), which they can recycle.

Interalveolar pores (of Kohn)

These are small pores lined by epithelium (usually type II alveolar cells), which cross interalveolar septa to link adjacent alveolar airspaces. Humans have up to seven pores per alveolus, ranging in size from 2 to 13 µm. These small passages may sustain the flow of air in the event of blockage of one of the alveolar ducts and also provide routes of migration for alveolar macrophages.

Alveolar macrophages

Alveolar macrophages are derived from circulating monocyte precursors. They originate in haemopoietic tissue in the bone marrow, migrate into the alveolar lumen from adjacent blood vessels and connective tissue, and wander about on the epithelial surfaces. They clear the respiratory spaces of inhaled particles which are small enough to reach the alveoli (hence their alternative name of 'dust cells'). Most of them migrate with their phagocytosed load to the bronchioles, where they are swept into the mucociliary rejection current and removed from the lung. Others migrate through the epithelium of the alveoli into the lymphatics which drain the connective tissue of the lung, and so pass into lymphoid tissue around the pulmonary lobules. Under normal conditions alveolar macrophages have a granular cytoplasm because they contain phagocytosed particles: in smokers the particles have a characteristic appearance, and are called tar bodies. When actively phagocytic, macrophages release proteases: if antiproteases (e.g. α₁-antitrypsin) that are normally present in the alveolar lining are deficient, macrophage activity may damage the lung. Alveolar macrophages are involved in the turnover of surfactant.

Alveolar macrophages can be recovered from sputum, and are of diagnostic importance if they appear abnormal. For instance, whenever erythrocytes leak from pulmonary capillaries, the macrophages that engulf the extravasated cells become brick red, and are detectable in ‘rusty’ sputum. They are typical of congestive heart failure, and often termed heart-failure cells. Macrophages that migrate back into the connective tissue of the lung settle in patches that are visible beneath the visceral pleura, e.g. carbon-filled cells give the lungs a mottled appearance. However, if the inhaled particles are abrasive or chemically active, they may elude macrophage removal and damage the respiratory surface, producing fibrosis and a concomitant reduction in the respiratory area. This occurs in many industrial diseases, e.g. pneumoconiosis, caused by coal dust, or asbestosis, where the long thin fibres of asbestos can cause considerable damage and may trigger fatal mesothelioma in the pleural lining.

Alveolar surfactant

The alveolar surface is normally covered by a film of pulmonary surfactant, which is a complex mixture, mainly of phospholipids (particularly dipalmitoylphosphatidylcholine and phosphatidylglycerol), with some protein and neutral lipid (Devendra & Spragg
Surfactant is stored in lamellar bodies and secreted in the form of tubular myelin (unrelated to myelin of the nervous system) by type II pneumocytes. It is recycled by type II pneumocytes, or cleared (i.e. phagocytosed) by alveolar macrophages. Clara cells of the bronchiolar epithelium are believed to secrete surfactant of a different composition.

Surface tension at the alveolar surface is very high, because the alveoli are minute. This opposes expansion during inspiration, and tends to collapse the alveoli in expiration. The detergent-like properties of pulmonary surfactant greatly reduce the surface tension, and make ventilation of the alveoli much more efficient.
TRACHEA AND BRONCHI

The trachea is a tube formed of cartilage and fibromuscular membrane, lined internally by mucosa. The anterolateral portion is made up of incomplete rings of cartilage, and the posterior aspect by a flat muscular wall. It is 10–11 cm long, and descends from the larynx (Fig. 57.7) from the level of the sixth cervical vertebra to the upper border of the fifth thoracic vertebra, where it divides into right and left principal (pulmonary) bronchi. It lies approximately in the sagittal plane, but its point of bifurcation is usually a little to the right. The trachea is mobile and can rapidly alter in length; during deep inspiration, the bifurcation may descend to the level of the sixth thoracic vertebra. Its external transverse diameter is typically 2 cm in adult males, and 1.5 cm in adult females. In children it is smaller, more deeply placed and more mobile. The lumen in live adults has an average transverse diameter of 12 mm, although this increases after death because the smooth muscle making up its posterior aspect relaxes. In the first postnatal year, the tracheal diameter does not exceed 4 mm, while during later childhood its diameter in millimetres is approximately equal to age in years. The transverse shape of the lumen is variable, especially in the later decades of life, and may be round, lunate or flattened. At bronchoscopy the posterior wall of the trachea bulges into the lumen and this is exaggerated in expiration and coughing. The distal end of the trachea is visible as a concave spur. A tracheal bronchus may occasionally arise from the lateral wall of the trachea, more frequently from the right side: it may be supernumerary or it may represent a displaced upper lobe airway.

TRACHEAL RELATIONS

Cervical part of the trachea

Anterior relations

The cervical trachea is crossed anteriorly by skin and by the superficial and deep cervical fasciae. It is also crossed by the jugular arch and overlapped by sternohyoid and sternothyroid. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomotic artery connects the bilateral superior thyroid arteries; below this and in front are the pretracheal fascia, inferior thyroid veins, thymic remnants and the thyroid ima artery (when it exists). In children the brachiocephalic artery crosses obliquely in front of the trachea at, or a little above, the upper border of the manubrium; the left brachiocephalic vein may also rise a little above this level.

Posterior relations

The oesophagus lies behind the cervical trachea, separating it from the
vertebral column and the prevertebral fascia.

*Lateral relations*

The paired lobes of the thyroid gland, which descend to the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries are lateral relations. The recurrent laryngeal nerves ascend on each side, in or near the grooves between the sides of the trachea and the oesophagus.

*Thoracic part of the trachea*

*Anterior relations*

As it descends through the superior mediastinum, the thoracic trachea lies behind the manubrium sterni, the attachments of sternohyoid and sternothyroid, the thymic remnants and the inferior thyroid vein. The brachiocephalic and left common carotid arteries come to lie on the right and left respectively of the trachea as they diverge upwards into the neck. At a lower level, the aortic arch, the brachiocephalic and left common carotid arteries, left brachiocephalic veins, deep cardiac plexus and some lymph nodes are all anterior to the trachea.

*Posterior relations*

The oesophagus is posterior to the trachea and separates it from the vertebral column.

*Lateral relations*

Laterally and on the right are the right lung and pleura, right brachiocephalic vein, superior vena cava, right vagus nerve and azygos vein. On the left are the arch of the aorta, and the left common carotid and left subclavian arteries. The left recurrent laryngeal nerve is at first situated between the trachea and aortic arch, and then lies in, or just in front of, the groove between the trachea and the oesophagus.
RIGHT MAIN BRONCHUS

The right principal bronchus is approximately 2.5 cm long, and is wider, shorter and more vertical than the left (Figs 57.7, 57.8, 57.12). These differences explain why inhaled foreign bodies enter the right principal bronchus more often than the left (these events are more common in children and they may present with breathlessness, unilateral wheeze or recurrent aspirations: a chest radiograph may show air trapping in the affected lobe). The right main bronchus gives rise to its first branch, the superior lobar bronchus, then enters the right lung opposite the fifth thoracic vertebra. The azygos vein arches over it, and the right pulmonary artery lies at first inferior, then anterior, to it. After giving off the superior lobar bronchus, which arises posterosuperior to the right pulmonary artery, the right main bronchus crosses the posterior aspect of the artery, enters the pulmonary hilum posteroinferior to it, and divides into a middle and an inferior lobar bronchus. Normal variants in the bronchial anatomy are occasionally seen and consist of either displaced or supernumerary airways (see Ghaye et al 2001). Abnormalities include a common origin of the right upper and middle lobe bronchi; an accessory cardiac bronchus; and a right lower lobe bronchus that may arise from the left main stem bronchus. These anatomical variants are largely asymptomatic, but occasionally may cause haemoptysis, recurrent infection and development of bronchiectasis of the airway.
Right superior lobar bronchus

The right superior lobar bronchus arises from the lateral aspect of the parent bronchus and runs superolaterally to enter the hilum; 1 cm from its origin it divides into three segmental bronchi.

Segmental anatomy

The apical segmental bronchus continues superolaterally towards the apex of the lung, which it supplies, and divides near its origin into apical and anterior branches. The posterior segmental bronchus serves the posteroinferior part of the superior lobe, passes posterolaterally and slightly superiorly, and soon divides into a lateral and a posterior branch. The anterior segmental bronchus runs anteroinferiorly to supply the rest of the superior lobe, and divides near its origin into a lateral and an anterior branch of equal size (Figs 57.5, 57.6).

Right middle lobar bronchus

The right middle lobar bronchus normally starts 2 cm below the superior lobar bronchus, from the front of right bronchus intermedius, and descends anterolaterally.
Segmental anatomy

The right middle lobar bronchus soon divides into a lateral and a medial segmental bronchus: these pass to the lateral and medial parts of the middle lobe respectively (Figs 57.5, 57.6).

Right inferior lobar bronchus

The right inferior lobar bronchus is the continuation of the principal bronchus beyond the origin of the middle lobar bronchus.

Segmental anatomy

At or a little below its origin from the principal bronchus, the right inferior lobar bronchus gives off a large superior (apical) segmental bronchus posteriorly. This runs posteriorly to the upper part of the inferior lobe, and then divides into medial, superior and lateral branches; the first two usually arise from a common stem. After giving off the superior segmental branch, the right inferior lobar bronchus descends posterolaterally. The medial basal segmental bronchus branches from its anteromedial aspect, and runs inferomedially to serve a small region below the hilum. The inferior lobar bronchus continues downwards and then divides into an anterior basal segmental bronchus, which descends anteriorly, and a trunk that soon divides into a lateral basal segmental bronchus, which descends posteriorly, and a posterior basal segmental bronchus, which descends posteriorly. In more than half of all right lungs a subsuperior (subapical) segmental bronchus arises posteriorly from the right inferior lobar bronchus 1–3 cm below the superior segmental bronchus, and is distributed to the region of lung between the superior and posterior basal segments (Figs 57.5, 57.6).
LEFT MAIN BRONCHUS

The left principal bronchus, which is narrower and less vertical than the right, is 5 cm long. Passing to the left inferior to the aortic arch, it crosses anterior to the oesophagus, thoracic duct and descending aorta; the left pulmonary artery is at first anterior and then superior to it. It enters the hilum of the left lung at the level of the sixth thoracic vertebra and divides into a superior and an inferior lobar bronchus.

Left superior lobar bronchus

The left superior lobar bronchus arises from the anterolateral aspect of its parent stem, curves laterally, and soon divides into two bronchi which correspond to the branches of the right principal bronchus as it supplies the right superior and middle lobes, except that on the left side both are distributed to the left superior lobe because there is no separate middle lobe.

Segmental anatomy

The superior division of the left superior lobar bronchus ascends 1 cm, gives off an anterior segmental bronchus, continues a further 1 cm as the apicoposterior segmental bronchus, and then divides into apical and posterior branches. The apical, posterior and anterior segmental bronchi are largely distributed as they are in the right superior lobe. The inferior division descends anterolaterally to the anteroinferior part of the left superior lobe (the lingula) and forms the lingular bronchus, which divides into superior and inferior lingular segmental bronchi. This is different from the pattern in the right middle lobe, where the corresponding distribution is lateral and medial (Figs 57.5, 57.6).

Left inferior lobar bronchus

The left inferior bronchus descends posterolaterally and divides to supply territories of the lung that are distributed in essentially the same manner as they are in the right lung.

Segmental anatomy

The superior (apical) segmental bronchus arises from the inferior lobar bronchus posteriorly 1 cm from its origin. After a further 1–2 cm, the inferior lobar bronchus divides into an anteromedial and a posterolateral stem. The latter divides into lateral and posterior basal segmental bronchi. The anterior basal segmental bronchus is an independent branch of the inferior lobar bronchus occasionally. A subsuperior (subapical) segmental bronchus arises posteriorly from the left inferior lobar bronchus sometimes (Figs 57.5, 57.6).
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Trachea

The trachea is supplied with blood mainly by branches of the inferior thyroid arteries. The thoracic portion of the trachea is also supplied by branches of the bronchial arteries that ascend to anastomose with the tracheal branches of the inferior thyroid arteries. Veins draining the trachea end in the inferior thyroid venous plexus. The lymph vessels pass to the pretracheal and paratracheal lymph nodes.

Bronchi

Bronchial arteries

The bronchial arteries supply oxygenated blood to maintain the pulmonary tissues. They are derived from the descending thoracic aorta either directly or indirectly (Baile 1996). The right bronchial artery is usually a branch of the third posterior intercostal artery. There are normally two left bronchial arteries (upper and lower) that branch separately from the thoracic aorta. The bronchial arteries accompany the bronchial tree and supply bronchial glands, the walls of the bronchial tubes and larger pulmonary vessels. The bronchial branches form a capillary plexus in the muscular tunic of the air passages which supports a second, mucosal plexus that communicates with branches of the pulmonary artery and drains into the pulmonary veins. Other arterial branches ramify in interlobular loose connective tissue and most end in either deep or superficial bronchial veins; some also ramify on the surface of the lung, forming subpleural capillary plexuses. Bronchial arteries supply the bronchial wall as far as the respiratory bronchioles, and anastomose with branches of the pulmonary arteries in the walls of the smaller bronchi and in the visceral pleura. These bronchopulmonary anastomoses may be more numerous in the newborn and are subsequently obliterated to a marked degree. In addition to the main bronchial arteries, smaller bronchial branches arise from the descending thoracic aorta: one of these may lie in the pulmonary ligament and may cause bleeding during inferior lobectomy.

Bronchial veins

Usually two on each side, the bronchial veins drain blood from larger bronchi and from hilar structures. They form two distinct systems. Deep bronchial veins commence as intrapulmonary bronchiolar plexuses that communicate freely with the pulmonary veins and eventually join a single trunk that ends in a main pulmonary vein or in the left atrium. Superficial bronchial veins drain extrapulmonary bronchi, visceral pleura and the hilar lymph nodes. They also communicate with the pulmonary veins and end in the azygos vein on the right and in the left superior intercostal or the accessory hemiazygos veins on
the left. Bronchial veins do not receive all the blood conveyed by bronchial arteries, some enters the pulmonary veins (see pp. 996–997). The main bronchial arteries and veins run on the dorsal aspect of the extrapulmonary bronchi.

**Lymphatic drainage**

The deep lymphatic plexus reaches the hilum by travelling along the pulmonary vessels and bronchi. In larger bronchi the deep plexus has submucosal and peribronchial parts, but in smaller bronchi there is only a single plexus that extends to the bronchioles. The walls of the alveoli have no lymphatic vessels.
INNERVATION

The anterior and posterior pulmonary plexuses innervate the trachea and the bronchi. The two plexuses are interconnected. The trachea is innervated by branches of the vagi, recurrent laryngeal nerves and sympathetic trunks. The nerves enter the lung as networks that travel along branches of the bronchi and pulmonary and bronchial vessels as far as the visceral pleura. Efferent vagal preganglionic axons synapse on small ganglia within the walls of the tracheobronchial tree: these may act as sites of integration and/or modulation of the input from extrinsic nerves, or permit some local control of aspects of airway function by local reflex mechanisms. The parasympathetic nervous system is the dominant neuronal pathway in the control of airway smooth muscle tone. Stimulation of cholinergic nerves causes bronchoconstriction, mucus secretion and bronchial vasodilation. Sympathetic nerves may control tracheobronchial blood vessels, but innervation of human airway smooth muscle by sympathetic-adrenergic fibres has yet to be convincingly demonstrated.
MICROSTRUCTURE OF THE CONDUCTING AIRWAYS

The conducting airways are lined internally by a mucosa, and the epithelium lies on a thin connective tissue lamina propria. External to this is a submucosa, also composed of connective tissue, in which are embedded airway smooth muscle, glands, cartilage plates (depending on the level in the respiratory tree), vessels, lymphoid tissue and nerves. Cartilage is present from the trachea to the smallest bronchi, but is absent (by definition) from bronchioles.

Epithelium

The epithelia of the trachea, bronchi and bronchioles are, in general, similar to each other, with graded variations in the numbers of different cell types. The extrapulmonary and larger intrapulmonary passages are lined with respiratory epithelium, which is pseudostratified, predominantly ciliated, and contains interspersed mucus-secreting goblet cells. There are fewer cilia in terminal and respiratory bronchioles, and the cells are reduced in height to low columnar or cuboidal. The epithelium of smaller bronchi and bronchioles is folded into conspicuous longitudinal ridges, which allow for changes in luminal diameter (Fig. 57.9). The epithelium in the respiratory bronchioles progressively reduces in height towards the alveoli, and is eventually composed of cuboidal, non-ciliated cells. Respiratory bronchioles have lateral pouches in their walls, which are lined with squamous cells, so providing an accessory respiratory surface.

Six distinct types of epithelial cell have been described in the conducting airways, namely, ciliated columnar, goblet, Clara, basal, brush and neuroendocrine. Lymphocytes and mast cells migrate into the epithelium from the underlying connective tissue.

Ciliated columnar cells

Ciliated columnar cells are the driving force of the mucociliary rejection current (escalator) in the bronchial tree. They vary from low to tall columnar, and each has up to 300 cilia projecting from the apical surface. The cilia extend into a watery fluid secreted by serous cells of the submucosal glands, but their tips are in contact with a more superficial layer of thicker mucus secreted by surface goblet cells and mucous cells in the submucosal glands. The rate of ciliary beating is usually 12–16 per second, although mechanical stimulation of the epithelial surface, and inflammatory mediators, increase the rate. In addition to tight junctions which seal the apical intercellular space from the airway lumen, the ciliated cells are coupled by gap junctions which allow a change in rate of beating to spread from stimulated cells to their neighbours (probably via calcium signalling) so that their metachronal coordination remains intact.

Goblet cells

Goblet cells are present from the trachea (6000–7000 per mm²) down to the smaller bronchi, but are normally absent from bronchioles. They contain an apical region full of large secretory vacuoles filled with mucinogen. When the epithelium is irritated, e.g. by tobacco smoke, there is an overall increase in the number of goblet cells, and they also extend into the bronchioles.
Clara cells

Clara cells are cuboidal non-ciliated cells with apices which bulge into the lumen. They contain numerous electron-dense secretory granules and many lysosomes. Clara cells produce surfactant lipoprotein and thus share functional similarities with the type II alveolar cell of pulmonary alveoli, although their secretory granules differ in structure and composition. They may also regulate ion transport.

Basal cells

Basal cells are small rounded cells that occur in parts of the airway lined by pseudostratified respiratory epithelium; they are mitotic stem cells for other epithelial cell types. Basal cells contact the basal lamina and are most frequent in the larger conducting passages.

Brush cells

Brush cells are slender, non-ciliated cells with characteristically long, stiff apical microvilli from which they derive their name. Although infrequent, they are present throughout all parts of the conducting airway passages, including the respiratory epithelium of the nasopharynx. They are in contact with afferent nerve fibres basally and are presumed to have a sensory receptor function.

Neuroendocrine cells

Neuroendocrine cells, also termed dense-core or small granule (Kulchitsky) cells, are found mainly in the basal part of the epithelium. They have a rounded shape and the cytoplasm basal to their nuclei contains numerous small dense-coated vesicles, approximately 150 nm diameter. They form part of the dispersed neuroendocrine system of amine precursor uptake and decarboxylation (APUD) cells. Neuroendocrine cells are most numerous in fetal lungs and their number decreases dramatically after birth. There appears to be little further change in their frequency during adult life, although they may proliferate in certain pulmonary diseases.

Lymphocytes

Small lymphocytes, mainly T cells derived from mucosa-associated lymphoid tissue in the walls of the passages, occur within the epithelium throughout the conducting airway tissues, particularly in the extrapulmonary portion: they are concerned with the immune surveillance of the epithelium. Clusters of lymphocytes sometimes lie beneath non-ciliated epithelial cells of the microfold (M-cell) type.

Mast cells

Mast cells are present within the basal regions of the epithelium. They resemble connective tissue mast cells, and their cytoplasmic histamine-containing granules are released in response to irritants, including inhaled allergens.

Submucosal glands

Tubuloacinar, seromucous glands are present in the submucosa of the trachea and bronchi and, to a lesser extent, in the larger bronchioles. They contain separate
mucous and serous cells, and are an important source of the mucous layer at the surface of the ciliated respiratory epithelium. Their secretions include mucins; the bacteriostatic substances lysozyme and lactoferrin; secretory antibodies (IgA) produced by plasma cells in the submucosal connective tissue; and protease inhibitors (e.g. α1-antitrypsin) important for neutralizing leukocyte-derived proteases, particularly elastase, in the respiratory tract. The secretory acini and tubules are surrounded by myoepithelial cells, which are innervated by autonomic fibres.

**Connective tissue and muscle**

Broad, longitudinal bands of elastin (Fig. 57.13) within the submucosa follow the course of the respiratory tree and connect with the elastin networks of the interalveolar septa (see Fig. 57.9). This elastic framework is a vital mechanical element of the lung, and is responsible for elastic recoil during expiration.
In the trachea and extrapulmonary bronchi, the smooth muscle is mainly confined to the posterior, non-cartilaginous part of the tracheal tube (Fig. 57.14). Along the entire intrapulmonary bronchial tree, smooth muscle forms two opposed helical tracts which become thinner and finally disappear at the level of the alveoli. The tone of these muscle fibres is under nervous and hormonal control: groups of muscle cells are coupled by gap junctions to spread excitation within fascicles.
Muscle cell contraction narrows the airway, while relaxation permits bronchodilation. Some tone normally exists in the muscular bands, which relax slightly during inspiration and contract during expiration, thereby assisting the tidal flow of air. Abnormal contraction may be caused by circulating smooth muscle stimulants or by local release of excitants such as serotonin, histamine and leukotrienes, which produces bronchospasm. Numerous mast cells are present in the connective tissue of the respiratory tree, especially towards the bronchioles.

**Cartilaginous support**

The trachea and extrapulmonary bronchi contain a framework of incomplete rings of hyaline cartilage which are united by fibrous tissue and smooth muscle (Fig. 57.14). Intrapulmonary bronchi contain discontinuous plates or islands of hyaline cartilage in their walls.

**Tracheal cartilages**

Tracheal cartilages vary from 16 to 20 in number. Anteriorly, each cartilage takes the form of an incomplete ring which surrounds approximately two-thirds of the tracheal circumference. Posteriorly, where the cartilages are deficient, the tube is flat and is completed by fibroelastic tissue and smooth muscle. The cartilages are horizontally stacked and separated by narrow intervals. They are typically 4 mm vertically, and 1 mm thick. Their external surfaces are vertically flat, and their internal surfaces are convex. Two or more cartilages often unite, partially or completely, and sometimes bifurcate at their ends. They may become calcified in the elderly. The cartilages are shorter, narrower and less regular in extrapulmonary bronchi, but they are generally similar in shape and arrangement.

The first and last tracheal cartilages differ from the rest (Fig. 57.7). The first cartilage is the broadest. It often bifurcates at one end and is connected by the cricotracheal ligament to the inferior border of the cricoid cartilage, with which it may blend. It may also blend with the second cartilage. The last cartilage is centrally thick and broad and its lower border, the carina, is a triangular hook-shaped process which curves down and backwards between the bronchi (Fig. 57.9). It forms an incomplete ring on each side, and encloses the start of a principal bronchus.

**Bronchial cartilages**

The irregularity of the cartilaginous plates in the extrapulmonary bronchi increases as they are traced distally, and as the major bronchi approach their lungs and lobes, the plates surround their dorsal aspects. In intrapulmonary bronchi, discontinuous plates of cartilage progressively form less and less of the bronchial wall, and they are not present in the bronchioles.
PULMONARY DEFENSIVE MECHANISMS

The respiratory tract presents a huge surface area that is vulnerable to desiccation, microbial invasion and the mechanical and chemical effects of inhaled particles. Inhaled air is humidified chiefly in the upper respiratory tract where it passes, with some turbulence, over the nasal and buccopharyngeal mucosae. The secretions of the various glands of the bronchial tree also help to prevent desiccation. Goblet cells secrete sulphated acid mucosubstances; cells in mucous glands beneath the epithelial surface contain mainly carboxylated mucosubstances, particularly those associated with sialic acid, although sulphated groups also occur; cells of serous glands contain neutral mucosubstances. Goblet cells respond mainly to local irritation, while tubular glands, both mucous and serous, are mainly under neural and hormonal control. Excessive or altered secretions may obstruct the flow of air. In addition to mucosubstances secreted by bronchial glands, antibacterial and antiviral substances, e.g. lysozyme, antibodies of the IgA type and possibly interferon, also appear in the secreted fluid.

Inhaled particles may be removed via the mucociliary rejection current. Cilia sweep the fluid overlying the surfaces of bronchioles, bronchi and trachea upwards at 1 cm/min, and much of the inhaled matter trapped in the viscous fluid may be removed in this way. Particles small enough to reach the alveoli may be removed by alveolar phagocytes (see p. 998). Alveolar epithelium has limited powers of regeneration but normally is continually replaced. The lifespan of alveolar squamous cells is approximately 3 weeks, and that of alveolar phagocytes is 4 days. Inhaled particles may also be cleared by the cough reflex.

Numerous lymphoid nodules occur in the bronchial lining. They provide foci for the production of lymphocytes and give local immunological protection against infection both by cell-mediated (T-cell) activities, and by the production of immunoglobulins (mainly IgA) from B cells, which are passed on to gland cells for secretion to the epithelial surface.

Anatomy of coughing

Coughing involves an initial deep inspiration, followed by forceful contraction of the expiratory muscles and diaphragm against a closed glottis. This leads to an abrupt rise in pleural pressure (6.5 to 13 kPa) and intra-alveolar pressure. Subsequent glottal opening causes a rapid peak expiratory flow of air, followed by some collapse of the trachea and central airways, which is responsible for the post-peak plateau in flow.

Coughing is initiated when mechanically and chemically sensitive vagal afferents innervating the airways are activated. Data from experimental studies suggest that the receptors innervated by these afferents may be
broadly divided into three groups: slowly (SAR) and rapidly (RAR) adapting stretch receptors and bronchopulmonary C fibres. The vagal afferents terminate centrally in largely nonoverlapping regions of the caudal half of the nucleus of the solitary tract; second order neurones from this nucleus terminate in respiratory-related regions of the medulla, pons and spinal cord. Afferent nerves innervating other viscera, and somatosensory nerves innervating the chest wall, diaphragm and anterior abdominal musculature are also likely be involved in regulating cough.

The identity of the afferent terminals in the airways is uncertain; receptors similar to taste buds are considered to be responsible at the laryngeal aditus, and some of the 'brush cells' of the respiratory epithelium appear to have neural contacts, and may therefore represent sensory cells with basal synaptic outputs (Widdicombe 2002). Other than the larynx, the carina and branching points of the tracheobronchial tree appear to be the most sensitive areas of the epithelium lining the airways.

For further details, see Kubin et al (2006) and Canning (2006).
**BRONCHOSCOPY**

Bronchoscopy allows the direct visualization of the vocal cords, trachea and major airways as far as the first division of the subsegmental airway. Occasionally bronchoscopy can also provide some information about structures adjacent to the airways, for example, significant subcarinal lymphadenopathy may cause splaying or widening of the carina. Bronchoscopy enables the acquisition of samples (e.g. bronchial lavage, bronchial brushings, bronchial and transbronchial biopsies), provides information about staging in lung cancer, and facilitates therapeutic procedures (e.g. foreign body removal, ablation of tumours and insertion of airway stents). The information obtained by continuous (spiral) volume CT scanning can be reconstructed to provide three-dimensional images which can be used to create endobronchial views (virtual bronchoscopy, Fig 57.15) or to demonstrate the pulmonary arteries.

CHAPTER 58 – Diaphragm

The diaphragm is a curved musculofibrous sheet that separates the thoracic from the abdominal cavity (Figs 58.1, 58.2). Its mainly convex upper surface faces the thorax, and its concave inferior surface is directed towards the abdomen. The positions of the domes or cupolae of the diaphragm are extremely variable because they depend on body build and the phase of ventilation. Thus the diaphragm will be higher in short, fat people than in tall, thin people, and overinflation of the lung, as occurs for example in emphysema, causes marked depression of the diaphragm. Usually, after forced expiration the right cupola is level anteriorly with the fourth costal cartilage and therefore the right nipple, whereas the left cupola lies approximately one rib lower. With maximal inspiration, the cupola will descend as much as 10 cm, and on a plain chest radiograph the right dome coincides with the tip of the sixth rib. In the supine position, the diaphragm will be higher than in the erect position, and when the body is lying on one side, the dependent half of the diaphragm will be considerably higher than the uppermost one.
Fig. 58.1  A, Abdominal aspect of the diaphragm. Note the apertures for the oesophagus and inferior vena cava and the aortic hiatus. The medial part of the right crus frequently consists of three components and extends further distally than the left crus. B, Trunk sectioned at the level of the tenth thoracic vertebra.
(From Sobotta 2006.)
ATTACHMENTS AND COMPONENTS

The muscle fibres of the diaphragm arise from the highly oblique circumference of the thoracic outlet: the attachments are low posteriorly and laterally, but high anteriorly. Although it is a continuous sheet, the muscle can be considered in three parts, sternal, costal and lumbar, which are based on the regions of peripheral attachment. The sternal part arises by two fleshy slips from the back of the xiphoid process, and is not always present. The costal part arises from the internal surfaces of the lower six costal cartilages and their adjoining ribs on each side, and interdigitates with transversus abdominis (see Fig. 54.14). The lumbar part arises from two aponeurotic arches, the medial and lateral arcuate ligaments (sometimes termed lumbocostal arches) and from the lumbar vertebrae by two pillars or crura.

The lateral arcuate ligament is a thickened band in the fascia that covers quadratus lumborum, and it arches across the upper part of that muscle. It is attached medially to the front of the transverse process of the first lumbar vertebra, and laterally to the lower margin of the twelfth rib near its midpoint. The medial arcuate ligament is a tendinous arch in the fascia that covers the upper part of psoas major. Medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is thus attached to the side of the body of the first or second lumbar vertebra. Laterally, it is fixed to the front of the transverse process of the first lumbar vertebra.

The crura are tendinous at their attachments, and blend with the anterior longitudinal ligament of the vertebral column. The right crus is broader and longer than the left, and arises from the anterolateral surfaces of the bodies and intervertebral discs of the upper three lumbar vertebrae. The left crus arises from the corresponding parts of the upper two lumbar vertebrae. The medial tendinous margins of the crura meet in the midline to form an arch, the median arcuate ligament, which crosses the front of the aorta at the level of the thoracolumbar disc; it is often poorly defined.

From these circumferential attachments, the fibres of the diaphragm converge into a
central tendon. Fibres from the xiphoid process are short, run almost horizontally and are occasionally aponeurotic. Fibres from the medial and lateral arcuate ligaments, and more especially those from the ribs and their cartilages, are longer. They rise almost vertically at first and then curve towards their central attachment. Fibres from the crura diverge, and the most lateral become even more lateral as they ascend to the central tendon. Medial fibres of the right crus embrace the oesophagus where it passes through the diaphragm, the more superficial fibres ascend on the left, and deeper fibres cover the right margin. Sometimes, a fleshy fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the vena caval opening, but this fasciculus does not continue upwards around the oesophageal passage on the right side.

The central tendon of the diaphragm is a thin but strong aponeurosis of closely interwoven fibres situated near the centre of the muscle, but closer to the front of the thorax, so that the posterior muscular fibres are longer. In the centre it lies immediately below the pericardium, with which it is partially blended. Its shape is trifoliate. The middle, or anterior, leaf has the form of an equilateral triangle with the apex directed towards the xiphoid process. The right and left folia are tongue-shaped and curve laterally and backwards, the left being a little narrower. The central area of the tendon consists of four well-marked diagonal bands fanning out from a thick central node where compressed tendinous strands decussate in front of the oesophagus and to the left of the vena cava.
RELATIONS

The upper surface of the diaphragm is related to three serous membranes. On each side, the pleura separates it from the base of the corresponding lung, and the pericardium is interposed between the middle folium of the central tendon and the heart. This latter area, which is almost flat, is referred to as the cardiac plateau and extends more to the left than the right. In anteroposterior view, the superior profile of the diaphragm rises on either side of the cardiac plateau to a smooth convex dome or cupola, the cupola on the right being higher and slightly broader than that on the left. Most of the inferior surface is covered by peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney and right suprarenal gland. The left side conforms to the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney and the left suprarenal (adrenal) gland. In view of these differences in the profile and anatomical relationships of the right and left sides of the diaphragm, the side should always be specified in clinical descriptions. At full inspiration, the right hemidiaphragm is found at the anterior sixth rib on a posteroanterior chest radiograph; the left hemidiaphragm is 1.5–2.5 cm lower than the right (see Fig. 55.16). Unilateral paralysis may be seen as a raised hemidiaphragm on a chest radiograph, but this sign should not be relied upon uncritically in clinical practice.
APERTURES

A number of structures pass between the thorax and abdomen via apertures in the diaphragm. There are three large openings, for the aorta, oesophagus and inferior vena cava, and a number of smaller ones (Fig. 58.2).

The aortic aperture is the lowest and most posterior of the large openings, and is found at the level of the lower border of the twelfth thoracic vertebra and the thoracolumbar intervertebral disc, slightly to the left of the midline. It is an osseo-aponeurotic opening defined by the diaphragmatic crura laterally, the vertebral column posteriorly and the diaphragm anteriorly. Strictly speaking, it lies behind the diaphragm and its median arcuate ligament (when present). Occasionally, some tendinous fibres from the medial parts of the crura also pass behind the aorta, converting the opening into a fibrous ring. The aortic opening transmits the aorta, thoracic duct, lymphatic trunks from the lower posterior thoracic wall and, sometimes, the azygos and hemiazygos veins.

The oesophageal aperture is located at the level of the tenth thoracic vertebra, above, in front and a little to the left of, the aortic opening. It transmits the oesophagus, gastric nerves, oesophageal branches of the left gastric vessels and some lymphatic vessels. The elliptical opening has a slightly oblique long axis, and is bounded by muscle fibres that originate in the medial part of the right crus and cross the midline, forming a 'chimney' approximately 2.5 cm long, which accommodates the terminal portions of the oesophagus. The outermost fibres run in a craniocaudal direction, and the innermost fibres are arranged circumferentially. There is no direct continuity between the oesophageal wall and the muscle around the oesophageal opening. The fascia on the inferior surface of the diaphragm is continuous with the transversalis fascia and is rich in elastic fibres. It extends upwards into the opening as a flattened cone to blend with the wall of the oesophagus 2–3 cm above the oesophago-gastric (squamocolumnar) junction. Some of its elastic fibres penetrate to the submucosa of the oesophagus. This peri-oesophageal areolar tissue is referred to as the phreno-oesophageal ligament. It connects the oesophagus flexibly to the diaphragm, permitting some freedom of movement during swallowing and ventilation while at the same time limiting upward displacement of the oesophagus.

The vena caval aperture, the highest of the three large openings, lies at about the level of the disc between the eighth and ninth thoracic vertebrae. It is quadrilateral, and located at the junction of the right leaf with the central area of the tendon, and so its margins are aponeurotic. It is traversed by the inferior vena cava, which adheres to the margin of the opening, and by some branches of the right phrenic nerve.

There are two lesser apertures in each crus: one transmits the greater, and
the other the lesser, splanchnic nerve. The ganglionated sympathetic trunks usually enter the abdominal cavity behind the diaphragm, deep to the medial arcuate ligament. Openings for minute veins frequently occur in the central tendon.

On each side of the diaphragm there are small areas where the muscle fibres are replaced by areolar tissue. One, between the sternal and costal parts, contains the superior epigastric branch of the internal thoracic artery and some lymph vessels from the abdominal wall and convex surface of the liver. The other, between the costal part and the fibres that spring from the lateral arcuate ligament, is less constant; when it is present, the posterosuperior surface of the kidney is separated from the pleura only by areolar tissue.

**Oesophageal reflux**

Reflux of gastric contents into the oesophagus, with risk of inhalation into the lungs, is normally prevented by a physiological antireflux barrier located at the gastro-oesophageal junction. The major components of this barrier are the specialized smooth muscle of the wall of the lower oesophagus and the encircling fibres of the crural diaphragm. See also Chapter 65.

**Hiatus hernia**

The diaphragm lends additional power to all expulsive efforts: sneezing, coughing, laughing, crying, urinating, defecating, and expelling the fetus from the uterus are all preceded by a deep inspiration. Similarly, a deep inspiration followed by closure of the glottis is a common preliminary to powerful recruitment of the trunk muscles, e.g. in lifting heavy weights, because the increased intra-abdominal pressure provides pneumatic bracing of the vertebral column. Repeated stress may eventually compromise the integrity of the hiatus, so that the muscular hiatal tunnel widens. Concomitant laxity of the phreno-oesophageal membrane allows the gastro-oesophageal junction to slide into the thorax; this is usually termed a sliding, or type I, hiatus hernia (Kahrilas 2001). Sliding hernias are typically acquired. They commonly occur in the fifth decade of life and are found in more than 50% of patients with gastro-oesophageal reflux, a condition that induces tonic contraction of the longitudinal oesophageal muscle, which further exacerbates the hiatus hernia. When the stomach herniates into the thorax alongside the oesophagus, it is termed a para-oesophageal, or type II, hiatus hernia.

**Congenital hernias/eventration**

Abdominal organs, usually the stomach, may herniate through the diaphragm into the thorax. There are three sites at which such hernias can occur: posterolateral (Bochdalek), subcostosternal (Morgagni) and oesophageal.

The most common is a posterolateral (Bochdalek) hernia, which occurs as a
result of a defect in the posterior diaphragm in the region of the tenth or eleventh ribs. It is more common on the left, and presents with abdominal contents in the left hemithorax at birth; clinically significant cases develop hypoxaemia and respiratory failure at birth. A chest radiograph demonstrates mediastinal shift to the contralateral side and the presence of the gastrointestinal contents in the thorax; the diagnosis should be made at routine prenatal ultrasound. Treatment involves decompression of the gastrointestinal contents and cardiopulmonary stabilization. Surgical repair is performed when the patient is stable, but prognosis is determined by the degree of accompanying pulmonary hypoplasia, severity of pulmonary vascular abnormalities and any associated congenital heart defects.

Subcostosternal hernia, first described by Morgagni, is uncommon and occurs through a defect in the anterior diaphragm just lateral to the xiphoid process. It is frequently asymptomatic.

Oesophageal hernia occurs as a result of a defect in the oesophageal aperture, so that part of the stomach herniates into the thorax. It is rarely congenital in origin, usually develops later in life, and is believed to be acquired.

Diaphragmatic trauma

Closed and penetrating thoracoabdominal injuries may result in rupture or laceration of the diaphragm. With closed injuries and diaphragmatic rupture, there may be subsequent herniation of the abdominal contents into the thorax. Spiral CT with planar reformation should be the primary investigation (Shanmuganathan et al 2000): MRI is usually performed when other imaging modalities have produced equivocal findings. Early operative repair is recommended in diaphragmatic trauma, because untreated cases are at risk of developing gastrointestinal obstruction or perforation. Patients with penetrating injuries may require additional assessment by thoracoscopy (Lowdermilk & Naunheim 2000).
VASCULAR SUPPLY

ARTERIES

The lower five intercostal and subcostal arteries supply the costal margins of the diaphragm while the phrenic arteries supply the main central portion of the diaphragm. The anastomotic arrangement (see p. 1010) ensures profuse blood supply.

Phrenic arteries

Two small phrenic vessels help to supply the diaphragm via the abdominal surface. They may arise separately from the aorta, just above its coeliac trunk, or by a common aortic stem, or from the coeliac trunk. Occasionally, one is from the aorta, the other from a renal artery. Each artery ascends laterally anterior to a crus of the diaphragm, near the medial border of the suprarenal gland. The left passes behind the oesophagus and then runs forwards on the left side of its diaphragmatic opening. The right phrenic artery passes posterior to the inferior vena cava, and then along the right side of its opening. Each phrenic artery divides into medial and lateral branches near the posterior border of the central tendon. The medial branch curves forwards to anastomose with its contralateral fellow in front of the central tendon and with the musculophrenic and pericardiacophrenic arteries. The lateral branch approaches the thoracic wall, and anastomoses with the lower posterior intercostal and musculophrenic arteries. The lateral branch of the right artery supplies the inferior vena cava, whereas the left sends ascending branches to the oesophagus. Invariably there is a communicating artery between the left gastric and inferior phrenic arteries.
VEINS

Phrenic veins

The phrenic veins follow the corresponding arteries on the inferior diaphragmatic surface. The right phrenic vein ends in the inferior vena cava. The left phrenic vein is often double: one branch ends in the left renal or suprarenal vein, the other passes anterior to the oesophageal opening to join the inferior vena cava.
INNERVATION

The diaphragm receives its motor supply via the phrenic nerves (Fig. 58.3). Sensory fibres are distributed to the peripheral part of the muscle by the lower six or seven intercostal nerves. The right crus of the diaphragm, the fibres of which divide to the right and left of the oesophageal opening, is innervated by both right and left phrenic nerves. There is some evidence that the crural fibres contract slightly before the costal part, and this may be functionally significant for non-respiratory tasks (Sharshar et al 2005).
Phrenic nerve

The phrenic nerve is a mixed nerve that provides the sole motor supply to the diaphragm. It is derived mostly from the fourth cervical ramus, but also receives contributions from the third and fifth cervical rami (see Fig. 43.6). The course of the cervical part of the phrenic nerve is described on page 456. Within the thorax, the phrenic nerve descends anterior to the pulmonary hilum, between the fibrous pericardium and mediastinal pleura, to the diaphragm, accompanied by the pericardiophrenic vessels. In its thoracic course, each phrenic nerve supplies sensory branches to the mediastinal pleura, fibrous pericardium and parietal serous pericardium. The right and left phrenic nerves differ in their intrathoracic relationships (Rajanna 1947).

Right phrenic nerve

The right phrenic nerve is shorter and more vertical than the left, and is separated at the root of the neck from the second part of the right subclavian artery by scalenus anterior. It subsequently descends lateral to the right brachiocephalic vein, the superior vena cava and the fibrous pericardium that covers the right surface of the right atrium and inferior vena cava, and divides just above or at the level of the diaphragm (Fig. 58.2).

Left phrenic nerve

At the root of the neck, the left phrenic nerve is commonly stated to leave the medial edge of scalenus anterior and to pass anterior to the first part of the left subclavian artery and behind the thoracic duct. However, sometimes the right and left nerves are symmetric in their cervical course, and so the left phrenic nerve may cross anterior to the second part of the left subclavian artery, separated from it by scalenus anterior at the level of the thoracic inlet. Thereafter, the left phrenic nerve crosses anterior to the left internal thoracic artery, descending across the medial aspect of the apex of the left lung and its pleura to the first part of the subclavian artery, which it crosses obliquely to reach a groove between the left common carotid and subclavian arteries. It passes anteromedially, superficial to the left vagus nerve just above the aortic arch and behind the left brachiocephalic vein, and then passes superficial to the aortic arch and the left superior intercostal vein, anterior to the left pulmonary hilum, to lie between the fibrous pericardium covering the surface of the left ventricle and the mediastinal pleura (see Fig. 56.1).

Diaphragmatic relationships

The right phrenic nerve passes through the central tendon of the diaphragm, either by the caval aperture or just lateral to it. The left phrenic nerve passes through the muscular part of the diaphragm anterior to the central tendon, just lateral to the left cardiac surface and more anterior than the right phrenic nerve.
At the diaphragm or slightly above it, each phrenic nerve supplies fine branches to the parietal pleura above, and the parietal peritoneum below, the central diaphragm. Typically, the trunk of each nerve then divides into three branches as it passes through the diaphragm. These are commonly arranged as follows (with some variation): an anterior (sternal) branch, which runs anteromedially towards the sternum and connects with its fellow; an anterolateral branch, which runs laterally anterior to the lateral leaf of the central tendon; a short posterior branch, which divides into a posterolateral ramus coursing behind the lateral leaf and a posterior (crural) ramus which supplies the crural fibres. Posterolateral and crural branches may arise separately from the phrenic nerve. These main branches may be submerged in diaphragmatic muscle or lie below it. They supply motor fibres to the muscle and sensory fibres to the peritoneum and pleura related to the central part of the diaphragm. They also relay proprioceptive fibres from the musculature. The right phrenic nerve supplies the part of the right crus to the right of the oesophagus, and the left phrenic nerve supplies the left crus and the part of the right crus that lies on the left of the oesophagus. Phrenic rami connect with branches of the coeliac plexuses on the inferior surface of the diaphragm, and there is a small phrenic ganglion on the right, at the junction of the plexuses. Rami from the plexuses supply the suprarenal glands and, on the right, the hepatic falciform and coronary ligaments, the inferior vena cava and, possibly (via connections with coeliac and hepatic plexuses), the gallbladder.

Lesions of the phrenic nerve

An appreciation of the location of the main branches of the phrenic nerves is important to avoid iatrogenic surgical damage. Radial incisions in the diaphragm from the costal margin to the oesophageal hiatus lead to diaphragmatic paralysis, whereas thoracoabdominal incisions in a circumferential manner in the periphery of the diaphragm do not involve any significant branches of the phrenic nerves and preserve diaphragmatic function. Similarly, incisions of the central tendon are safe.

Division of the phrenic nerve in the neck completely paralyses the corresponding half of the diaphragm, which atrophies. If an accessory phrenic nerve exists, section or crushing of the main nerve as it lies on scalenus anterior will not produce complete paralysis. The phrenic nerve may be involved with traumatic lesions of the upper brachial plexus. Historically, it was deliberately injured in order to collapse, and hence rest, the lung in patients with pulmonary tuberculosis. Cardiac surgery is one of the most common medical causes of phrenic nerve injury, especially as a result of the instillation of saline slush for myocardial preservation. Other causes include thoracic surgery, tumours of the lung or mediastinum, and infections such as polio. Respiratory muscle weakness of rapid onset is a feature of Guillain–Barré syndrome.

Phrenic nerve damage leads to paradoxical movement of the diaphragm that is best observed fluoroscopically, with the patient first in the upright position (diaphragm unloaded), and then supine with a small weight on the abdomen.
Diaphragmatic paralysis can also be assessed by ultrasound examination with a sniff manoeuvre. The 'gold standard' for assessment of the phrenic nerve/diaphragm unit is electrical or magnetic stimulation of the phrenic nerve with recording of the compound muscle action potential and/or the transdiaphragmatic pressure. Electrical stimulation of the diaphragm, by 'pacing' of one or both phrenic nerves, has been used with some success in infants with central alveolar hypoventilatory syndrome ('Ondine's curse') and in patients with high cervical lesions of the spinal cord, in whom the diaphragm is paralysed but the lower motor neurones are intact. Electrodes are placed adjacent to the nerves, sometimes in the neck but more usually in the chest, and a ventilatory rhythm is established by trains of stimuli delivered by an implanted device. Because this is an unphysiological way of recruiting the muscle, the fibres must be 'conditioned' during the initial period of stimulation, so that they acquire the necessary resistance to fatigue.

**Referred pain**

Diaphragmatic pain is frequently felt at the tip of the shoulder, reflecting common nerve root origins in the neck. It usually occurs when there is inflammation of the diaphragmatic pleura, e.g. in basal pneumonia, pleural effusions or malignant disease.

**Accessory phrenic nerve**

The accessory phrenic nerve is described in Chapter 28.
ANATOMY OF BREATHING

Breathing is a highly coordinated abdominal and thoracic process. The diaphragm is the major muscle of inspiration, responsible for approximately two-thirds of quiet breathing in healthy humans. The external intercostal muscles are most active in inspiration, and the internal intercostals, which are not as strong, are most active in expiration. Increasing the vertical, transverse and anteroposterior dimensions of the chest increases the volume of the pleural space, and the resulting decrease in intrapleural pressure draws air into the lungs. During expiration, the diaphragm relaxes and moves superiorly. Air is expelled from the lungs and the elastic recoil of the lung creates a subatmospheric pressure that returns the lateral and anteroposterior dimensions of the thorax to normal (De Troyer & Estenne 1988, Celli 1998).

During inspiration, the lowest ribs are fixed, and contraction of the diaphragm draws the central tendon downwards. In this movement, the curvature of the diaphragm is scarcely altered. The cupolae move downwards and a little forwards almost parallel to their original positions. The associated downward displacement of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this extensibility is soon reached. The central tendon, its motion arrested by the abdominal viscera, then becomes a fixed point from which the fibres of the diaphragm continue to contract. This causes the second to tenth ribs to be elevated and the inferior portions of the ribs are turned outwards as a result of direct transmission of pressure through the zone of apposition (Fig. 58.4). The medial aspect of the rib is elevated and this increases the transverse dimension of the chest in the same manner as a bucket handle swinging outwards (Fig. 58.5A). This effect is most evident in the lower ribs (seventh to tenth ribs). Movements at the costovertebral joints cause elevation of the anterior ends of the ribs that push the body of the sternum and the upper ribs forwards. This ‘pump handle’ movement is most evident in the superior ribs (second to sixth ribs) and increases the anteroposterior dimension of the thorax (Fig. 58.5B). The right cupola of the diaphragm, which lies on the liver, has a greater resistance to overcome than the left, which lies over the stomach, and so the right crus and the fibres of the right side are more substantial than those of the left. The balance between descent of the diaphragm, protrusion of the abdominal wall (‘abdominal’ breathing), and elevation of the ribs (‘thoracic’ breathing) varies in different individuals and with the depth of ventilation. The thoracic element is usually more marked in females, but increases in both sexes during deep inspiration.
Fig. 58.4 Inspiratory movements: pressure changes during inspiration. (Adapted from Drake, Vogl and Mitchell 2005.)
Diaphragmatic excursion is typically 1.5 cm in quiet breathing. During deep ventilation, the maximum movement ranges from 6 to 10 cm. After a forced inspiration, e.g. when breathing is partially obstructed, the right cupola of the diaphragm can descend to about the level of the eleventh thoracic vertebra, while the left cupola may reach the level of the body of the twelfth thoracic vertebra. After a forced expiration, the right cupola of the diaphragm is level anteriorly with the fourth costal cartilage, laterally with the fifth, sixth and seventh ribs, and posteriorly with the eighth rib, and the left cupola is a little lower.

The level of the diaphragm is affected by the phase and depth of ventilation, and by the degree of distension of the stomach and intestines and the size of the liver. Radiographs show that the height of the diaphragm within the thorax also varies considerably with posture. It is highest when the body is supine, and in this position it performs the greatest ventilatory excursions with normal breathing. When the body is erect, the diaphragm is lower, and its ventilatory movements become smaller. The diaphragmatic profile is still lower in the sitting posture, and ventilatory excursions are smallest under these conditions. When the body is horizontal and on one side, the two halves of the diaphragm do not behave in the same way. The uppermost half sinks to a lower level than that seen when sitting, and moves little with ventilation. The lower half rises higher in the thorax than it does even in the supine position, and its ventilatory excursions are considerably greater. Changes in the level of the diaphragm with alterations in posture explain why patients with severe dyspnoea are most comfortable, and least short of breath, when sitting up.

The primary role of the intercostal muscles is to stiffen the chest wall, preventing paradoxical motion during descent of the diaphragm in inspiration. This becomes most obvious immediately after high spinal injury, when there is flaccid paralysis of the entire trunk and only the diaphragm is left functioning. In a healthy adult with a vital capacity of 4.5 L, some 3 L is accounted for by diaphragmatic excursion. Immediately after high spinal injury, the vital capacity decreases to about 300 mL, even though the diaphragm is moving maximally, because some 2.7 L is lost by paradoxical incursion of the flaccid chest wall as the diaphragm descends. With time (usually several weeks), the paralysis becomes spastic, stiffening the chest wall, and the vital capacity increases towards its phrenic limit of about 3 L.

In the same way, high spinal injury reveals the role of the abdomen in inspiration and
expiration. The abdominal musculature plays a major role in active expiration in man. During the flaccid stage of high spinal paralysis, the only mechanisms available for returning the relaxed diaphragm into the thorax on expiration are passive recoil of the lungs and chest wall, and the weight of the abdominal viscera. The latter is the most important, and operates only when patients are lying down. If they are sat up or raised upright, they are unable to breathe out. Trussing the abdomen with an elastic binder can help such patients. Conversely, when paralysis becomes spastic, the stiff abdominal wall opposes inspiration.

The role of the abdomen in breathing is often underestimated. If, for example, the anterolateral wall were made of steel and linked the pelvic rim rigidly to the costal margins, inspiration would be impossible. The diaphragm could not descend (because the abdominal contents are incompressible), and the ribs could not rise (because the links to the pelvis would be inextensible). During normal breathing, the abdomen relaxes as the diaphragm contracts. It is possible to oppose this motion by tensing the abdomen, as in the 'beach posture' adopted to exaggerate the size of the chest. In this case, the abdominal contents fix the central tendon of the diaphragm, so that it raises the ribcage as it contracts, but it is a condition of that manoeuvre that the gap between the ribs and the pelvic rim widens.

The ventilatory muscles must also work during sleep, when the pharyngeal muscles relax and upper airway resistance increases. It is now appreciated that in some people, particularly the obese, this relaxation can lead to periodic apnoea and marked hypoxia during sleep, implying that the pharyngeal muscles play an important ventilatory role in waking life. It is also clear that although ventilatory muscles rarely tire in normal life, they do fatigue when placed under abnormal loads, e.g. in chronic obstructive pulmonary disease.

The different pulmonary regions do not all move equally in ventilation. In quiet ventilation, the juxtahilar part of the lung scarcely moves and the middle region moves only slightly. The superficial parts of the lung expand the most, and the mediastinal surface, posterior border and apex move less, because they are related to less movable structures. The diaphragmatic and costomediastinal regions expand most of all. Most of the volumetric change during ventilation occurs in the alveoli.

CHAPTER 59 – Development of the thorax

THORACIC WALL AND DIAPHRAGM

The thorax as an entity is not apparent in embryos until the end of the embryonic stage of development (stage 23). It develops around the early pericardial cavity and the associated pericardioperitoneal canals (Fig. 59.1A; see Fig. 59.3A). The pericardioperitoneal canals give rise to the pleural cavities surrounding the lungs and that part of the peritoneal cavity surrounding the lower end of the foregut, which becomes the oesophagus, stomach and duodenum within the thoracic cage. Later these portions of peritoneal cavity are sequestered into the abdominal cavity by the development of the diaphragm.

Fig. 59.1 A. The arrangement of the epithelial populations in an embryo at about stage 11. The future thoracic region lies caudal to the pharynx and extends to the upper part of the septum transversum. B. The heart is shown in situ within the pericardial cavity. Venous tributaries return blood from the body, yolk sac and placenta and arterial trunks pass each side of the pharynx. C. The respiratory diverticulum arises in the midline from the lower portion of the pharynx and lung buds extend dorsally into the pericardio-peritoneal canals.
In stage 14 embryos, the heart is at the level of the upper cervical somites and above the upper limb buds. The thoracic somites are opposite the midgut. The putative thoracic region contains the pericardial cavity ventrally and the pericardioperitoneal canals posteriorly, on each side of the foregut. The future pleural cavities are as yet undefined regions of the pericardioperitoneal canals. Below the heart, septum transversum mesenchyme (see Fig. 73.5A) that has arisen from the caudal pericardial wall is being invaginated by endodermal epithelial cells from the foregut hepatic primordium.
The heart and pericardial cavity are relatively large in the early embryo (Fig. 59.1B; see Fig. 59.3A). Throughout development the lungs remain unexpanded and do not achieve their full size within the thorax, reflecting the fact that the placenta, and not the lungs, is the organ of fetal respiration. The lower partition of the thorax, the diaphragm, can be identified in stage 13 embryos; it migrates caudally in line with the craniocaudal progression of development and the elongation of the neck. The parietal pericardium remains attached to the diaphragm as it descends.

For the lungs to inflate and deflate, they must be surrounded by a complete pleural cavity slightly larger than the capacity of the lungs. The synchronous development of the thoracic cage, diaphragm and the pleural cavities is therefore of vital importance for the normal development of the lungs and postnatal functioning of the respiratory system. Before birth, fetal breathing movements may be observed using ultrasonography. These can have no respiratory function, but it is thought that these phasic changes lead to the release of growth factors which promote normal lung development. These movements require an intact thoracic and abdominal cavity, so that the diaphragm can descend towards the rigid pelvic bowl, pushing out the abdominal wall. In conditions where this is not the case, for example omphalocele, the lungs may be smaller than normal. Other causes of interference with these movements include neuromuscular disorders of antenatal onset, such as severe spinal muscular atrophy and myotonic dystrophy inherited from the mother, and reduced volume of amniotic fluid, for example in Potter's syndrome (bilateral renal agenesis, oligohydramnios sequence).

The lung buds are invested by splanchnopleuric mesenchyme derived from the medial walls of the pericardioperitoneal canals, whereas the lateral walls produce somatopleuric mesenchyme, which contributes to the body wall. This latter mesenchyme is penetrated by the developing ribs which arise from the thoracic sclerotomes. In the midline, the somatopleuric mesenchyme gives rise to the sternum and costal cartilages. The bony and cartilaginous cage provides insertions for the intercostal muscles, which arise from the ventrolateral edge of the epithelial plate of the somites. The somatopleuric coelomic epithelium, after its proliferative phase, gives rise to the mesothelium of the parietal layer of pleura.

As the lung buds project into the pericardioperitoneal canals (Figs 59.1C, 59.2A), they subdivide them into primary pleural coeloms around the lung buds cranially, and paired peritoneal coeloms caudally, which are continuous with the wider peritoneal coelom around the mid- and hindguts. The communications with the pericardial and peritoneal coeloms become termed the pleuropericardial and pleuroperitoneal canals, respectively. When separation between these fluid-filled major coelomic regions is advancing towards completion, they are named the pericardial, pleural and peritoneal cavities. In early embryos, the cavities retain substantial volumes of fluid and their walls are separate: they provide the route for a primitive type of circulation until superseded by the blood vascular system. In later fetal and postnatal life, the cavity walls are coapted, so that a mere microscopic film of serous fluid intervenes between them.
Fig. 59.2 A, Dorsolateral view of the foregut between the pericardio-peritoneal canals. The respiratory diverticulum arises from the ventral side of the pharynx and grows caudally. Bilateral lung buds extend dorsally into the pericardio-peritoneal canals dorsolaterally. Later changes in position of the common cardinal veins contribute to the formation of the pericardio-pleural membranes cranial to the developing lungs whereas folds of coelomic epithelium, pleuroperitoneal membranes, separate the pleural cavities from the peritoneal cavity. B, Components of the diaphragm.

A curved elevation of tissue, the pulmonary ridge, develops on the lateral wall of the pleural coelom and partly encircles the pleuropericardial canal. The ridge is continuous with the dorsolateral edge of the septum transversum. The developing lung bud abuts on the ridge, which as a result divides into two diverging membranes meeting at the septum transversum. One is cranially placed and termed the pleuropericardial membrane (Fig. 59.2A); embedded within it are the common cardinal vein and phrenic nerve, which reach the septum transversum by this route. The other membrane, caudally placed, is termed the pleuroperitoneal membrane (Fig. 59.2A,B). As the apical part of the lung forms, it invades and splits the body wall and extends cranially on the lateral aspect of the common cardinal vein, preceded by an extension from the primary pleural coelom to form part of the secondary, definitive, pleural sac. In this way the common cardinal vein and the phrenic nerve come to lie medially in the mediastinum. The pleuropericardial canal, which lies medial to the vein, is gradually narrowed to a slit, which is soon obliterated by the apposition and fusion of its margins. Closure occurs early and is mainly effected by the growth and expansion of the surrounding viscera (heart and great vessels, lungs, trachea and oesophagus), and not by active growth of the pleuropericardial membrane across the opening to the root of the lung.

In addition to its extension in a cranial direction, the lung and its associated visceral and parietal pleurae also enlarge ventromedially and caudodorsally. With the ventromedial extension, the lungs and pleurae therefore excavate and split the somatopleuric mesenchyme over the pericardium, separating the latter from the ventral and lateral thoracic walls (Fig. 59.3B–D). The ventrolateral fibrous pericardium, parietal serous pericardium and mediastinal parietal pleura, although topographically deep, are therefore somatopleuric in origin.

**Congenital disorders of the chest wall**

The dorsal portion of the thorax is derived from somites, the sclerotomal portions of which form the thoracic vertebrae and ribs (Ch. 44). Vertebral anomalies, including formation of hemivertebrae and block vertebrae (where cranial and caudal sclerotomal halves do not separate), may contribute to scoliosis. Five percent of scoliosis is congenital; it may be associated with multiple other anomalies, e.g. the VACTERL (Vertebral; Anorectal; Cardiac; Tracheal; Esophageal; Renal; Limb) association or with congenital syndromes such as Marfan’s and congenital neurofibromatosis. The diagnosis may be missed at birth. There are a number of syndromes in which the chest wall does not develop properly, and the lungs are consequently hypoplastic.
These include Jeune’s syndrome, asphyxiating thoracic dystrophy (an autosomal recessive condition which may be associated with short limb dwarfism and polydactyly). Rib cage abnormalities also occur in thanatrophic dwarfism, achondroplasia, chondroectodermal dysplasia and giant exomphalos. Many of these conditions are fatal soon after birth; milder forms may improve with time, but affected individuals may need prolonged respiratory support.
DIAPHRAGM

The separation of the pleural and peritoneal cavities is effected by development of the diaphragm, which forms from a portion of the septum transversum mesenchyme above the developing liver (Fig. 59.2A,B). The septum transversum is a population of mesenchymal cells which arises from the coelomic wall of the caudal part of the pericardial cavity. As the population proliferates, it forms a condensation of mesenchyme, caudal to the pericardial cavity and extending from the ventral and lateral regions of the body wall to the foregut. Dorsal to it on each side are the relatively narrow pleuroperitoneal canals. The endodermal hepatic bud grows into the caudal part of the septum transversum, whereas the cranial portion will form the diaphragm.

The oesophagus and stomach are medial to the pleuroperitoneal canals. As development proceeds, the lower portion of the oesophagus inclines ventrally anterior to the descending thoracic aorta. Although the oesophagus has no true ventral or dorsal mesentery, in descriptions of diaphragmatic development the portion of mesenchyme between the oesophagus and aorta at the level of the forming diaphragm is often homologized with part of a dorsal meso-oesophagus. The pleuroperitoneal membranes, which remain small, are dorsolateral to the canals, and the mesonephric ridges, suprarenal glands and gonads are dorsal. Just as the enlargement of the pleural cavity cranially and ventrally is effected by a process of burrowing into the body wall, so is its caudodorsal enlargement. The expanding pleural cavities extend into the mesenchyme dorsal to the suprarenal glands, the gonads and (degenerating) mesonephric ridges. Thus somatopleuric mesenchyme is peeled off the dorsal body wall to form a substantial portion of the dorsolumbar part of the diaphragm (Fig. 59.3C). The pleuroperitoneal canal is closed by the fusion of its edges, which are carried together from posterolaterally to anteromedially by growth of the organs surrounding it, in particular by growth of the suprarenal gland. The right pleuroperitoneal canal closes earlier than the left, which presumably explains why an abnormal communication persisting between the pleural and peritoneal cavities is more frequently encountered on the left.

While these changes are occurring, the septum transversum undergoes a progressive alteration in relative position. The dorsal border of the septum transversum which initially lies opposite the second cervical segment, migrates caudally as the embryo grows and the heart enlarges. At first the ventral border moves more rapidly than the dorsal, but after the embryo has attained a length of 5 mm, the dorsal border migrates more rapidly. When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (C3, 4 and 5) and portions of the corresponding myotomes, grow into it and accompany it in its later migrations. The dorsal
border of the septum transversum does not come to lie opposite the last thoracic and first lumbar segments, the final position occupied by some of the dorsal attachments of the diaphragm, until the end of the second month. The main derivatives of the central part of the diaphragm lie at considerably more cranial levels.

The diaphragm is therefore composed of the dorsal mesooesophagus and paired pleuropertitoneal membranes (posteriorly); septum transversum mesenchyme (ventrally); and excavated body wall (posteriorly and laterally).

**Diaphragmatic herniae**

Diaphragmatic herniae may result from failure of fusion of the component parts or from a primary defect. Posterolateral defects (Bochdalek's hernia) are the most common (85–90%) and may be bilateral (5%) or unilateral. Of the unilateral defects, the left side is more commonly affected (80%). Although these hernias have been attributed to failure of fusion of the pleuropertitoneal membrane, there is increasing evidence that the primary abnormality is lung hypoplasia, and the herniation of the abdominal contents is secondary, which has important implications for treatment (Jesudason 2002). A non-muscular membranous sac, possibly derived from the pleuropertitoneal canal wall is present in 10–15% of cases, signifying the early occurrence of this lesion prior to closure of the pleuropertitoneal canal. Hernias between the costal and sternal origins (Morgagni hernia) are rare (1–2%). Midline defects in the central tendon arise from septum transversum defects. The incidence of congenital diaphragmatic hernias is about 1 : 3000 to 1 : 5000 in neonates, with a prenatal incidence of 1 : 2000.

Diaphragmatic hernias can usually be diagnosed by antenatal ultrasound examination. The presence of bowel in the thorax and mediastinal shift may be seen. The main causes of death in babies with diaphragmatic hernias are pulmonary hypoplasia and hypertension. Pulmonary hypoplasia is related to the abnormal branching of the airways both ipsilaterally and contralaterally, resulting in the formation of reduced numbers of alveoli. Pulmonary hypertension is related to pulmonary hypoplasia, and also to the increased muscularization and reactivity of the pulmonary circulation. There may be associated abnormalities, including trisomy 13 and 18, and diaphragmatic hernia may be part of a number of syndromes, many of which may lead to termination of the pregnancy or to death of the neonate.

Diaphragmatic eventration is a condition in which a (usually) right-sided abnormal diaphragmatic silhouette is seen on X-ray with an abnormal medial bulge into the thorax. This is a benign condition, often a chance finding, and usually requiring no treatment: it is occasionally associated with rib and cardiac abnormalities.
OESOPHAGUS

The development of the oesophagus is described in Chapters 35 and 73. Failure of separation of the oesophagus and trachea is described on page 1036. Oesophageal atresia and tracheo-oesophageal fistula may present antenatally with polyhydramnios due to failure of fetal swallowing, and choking and inability to swallow saliva in the neonatal period.

Neonatal thorax and diaphragm

A number of differences between the neonatal and adult thorax and diaphragm are significant in early postnatal life, especially in the preterm infant. The full-term neonatal thorax has a rounded circumference whereas the adult profile is dorsoventrally flattened. The compliance of the adult chest wall and lung are approximately equal, but the neonatal chest wall is up to five times more compliant than the lungs and so is easily deformable: indrawing of the chest wall is an important sign of increased work of breathing in the neonate. The diaphragm is relatively flat at birth and gains its dome shape as the thorax and abdominal viscera grow. The arrangement of the ribs and diaphragm in the neonate means that contraction of the diaphragm pulls the compliant ribs inwards, which does not contribute to inspiration and leads to chest distortion, and which may be opposed by the stabilizing action of the expiratory muscles. The neonatal diaphragm exhibits an exaggerated asymmetric movement: the posterior portion shows a considerably greater excursion than the anterior portion.

A neonate undertakes relatively greater work in order to breathe, and is much more vulnerable to developing respiratory muscle fatigue and respiratory muscle failure than an adult. Experimental animal studies suggest that neonates may be especially vulnerable to respiratory muscle failure because of the initial immaturity of synapses. Moreover, myosin isoforms are developmentally regulated in the diaphragm: the reduced power output and work performance of the newborn diaphragm may reflect these molecular differences.

In expiration, there may be active braking of airflow, caused by inspiratory muscle activity and partial constriction of the larynx: this produces grunting on expiration especially if the lungs are stiff, for example in neonatal respiratory distress. A very preterm neonate is difficult to study, but respiration is likely to be even more compromised by the compliant chest wall and lack of reserve than it is in the term newborn (Mortola 2002).

At all ages, there is a reduction, if not loss, of tonic intercostal activity during rapid eye movement (REM) sleep. The mechanism is believed to be related to a descending spinal inhibition of the muscle spindle system. In addition, although during REM sleep the diaphragm descends further, this inspiratory
effort is dissipated in sucking in the ribs and enlarging the abdomen, thus the rib cage and abdominal ventilatory movements become out of phase. The neonate is at particular risk in this respect, because the chest wall is flexible, and much of the infant sleep activity is of the REM type. Furthermore, the upper airway musculature may lose tone during REM sleep, so that the soft tissues of the pharynx are sucked in during inspiration, limiting the cross-sectional area of the upper airway, and further increasing the work of breathing.
HEART AND GREAT VESSELS

Cardiac differentiation and morphogenesis are intimately related processes, achieved by a highly complicated transcriptional network. The cardiac transcription factor Nkx2–5, which has a homogeneous distribution over the embryonic heart tube, is generally important for cardiac-specific gene expression. In the human, mutations in this factor cause atrial septal defects and disturbances of atrioventricular conduction; in Drosophila the heart will not form in its absence. The recent discovery of the involvement of the role of T-box transcription factors, which are locally expressed, provides some evidence of the further complexity of patterning the heart. Whereas Tbx5 confers caudo-cranial positional information over the heart tube, thereby determining the regional development of the cardiac chambers along these axes, Tbx2 and 3 prevent regional formation of the cardiac chambers, permitting the myocardium in these regions to differentiate into the conduction system. Tbx18 is involved in the development of the sinus venosus and Tbx1 in the development of the outflow tract of the heart.

A number of terms must be specified before development of the heart and discussion of the cardiac chambers can be described. The inflow tract of the heart starts at the transition of the systemic tributaries (sinus venosus) into the primary heart tube. Within the straight heart tube, one atrial and one ventricular chamber are initially discerned, separated by an atrioventricular canal. The inflow tract thus connects the sinus venosus with the forming atrium, whereas the outflow tract connects the ventricle with the aortic sac; a proximal portion (close to the ventricle) and a distal portion can be defined within the outflow tract.

CELLS THAT GIVE RISE TO THE HEART

The heart is formed from tissues derived from the midline splanchnopleuric coelomic epithelium with later contributions from neural crest mesenchyme. The splanchnopleuric coelomic epithelium gives rise to the myocardium, including the conduction system of the heart, and the endocardium, including its derived cardiac mesenchymal population which produces the valvular tissues of the heart. Splanchnopleuric coelomic epithelium is also the source of the epicardium, coronary arteries and interstitial fibroblasts.

Primitive cardiac myocytes can first be seen in embryos at stage 9. During the onset of neurulation and somitogenesis, the intraembryonic coelom forms across the midline, initially above the endoderm, in a horse shoe-shaped area termed the cardiac crescent (Fig. 59.4). As the head fold emerges, the coelom undergoes a reversal, so that the future pericardial cavity comes to lie ventral to the endodermal foregut (Figs 59.1, 59.5). The splanchnopleuric wall of the pericardial coelom, subjacent to the endoderm, provides a germinal epithelium that produces early cardiac myocytes. It is characterized by the expression of myocardial specific markers, such as cardiac myosin heavy chain. This initial origin of myocardial cells is termed the primary heart-forming field, distinguishing it from later myocardial additions from mesenchyme localized central and peripheral to the cardiac crescent on the embryonic disc, termed the second heart-forming field (Fig. 59.4). It is not yet known whether these two sources of myocardium represent distinct myocardial lineages, or a single part which develops into separate components later on.
Fig. 59.4 A. The early embryonic disc viewed from a dorsolateral aspect showing the position of the primary heart-forming field relative to the surface ectoderm of the trilaminar disc. B. The rostral end of the unfolded embryonic disc from a dorsal aspect showing the position of the mesenchymal populations which will give rise to the primary heart-forming field, septum transversum mesenchyme and second heart-forming field.
The endocardium also develops during stage 9 from the coelomic splanchnopleuric epithelium. Cells arise singly close to the ventro-lateral edges of the cranial intestinal portal and form an endocardial plexus between the splanchnopleuric coelomic epithelium and the foregut endoderm. These groups of cells are now termed angioblastic mesenchyme; they are amongst the earliest intraembryonic vascular precursors to appear and express markers for the endothelial cell lineage. The cells aggregate to form an epithelium, the endocardium, which encloses small cavities which coalesce in the vicinity of the developing foregut to establish bilateral, hollow endocardial tubes. The latter fuse across the midline progressively, commencing at the outflow tract, or arterial pole, and extending to the inflow tract, or venous pole (Fig. 59.5). By stage 10 a single endocardial tube is present and is almost completely surrounded by myocardial cells. This arrangement of an outer myocardial sleeve containing an inner endocardial tube constitutes the primary heart tube. The inner endocardial epithelium induces the myocardial cells to synthesize specific extracellular matrix proteins which form a fine extracellular reticulum that holds the endocardial tube apart from the developing myocardium. Close to the foregut endoderm, the myocardial cells at the reflections of the pericardial splanchnopleuric epithelium form the dorsal mesocardium, which may stabilize the developing endothelium and promote the fusion of the bilateral endocardial tubes. The dorsal mesocardium encompasses a mesenchymal population specifically referred to as mediastinal mesenchyme, and is contiguous with the splanchnopleuric mesenchyme surrounding the embryonic foregut.

Much later in heart development, neural crest cells, arising from the region between the otic vesicle and the caudal limit of somite three, grow into the outflow tract of the heart. They are believed to play a role in the spatio-temporal regulation of the division
of the outflow tract into the aortic and pulmonary pathways, and the development of the muscular sub-pulmonary infundibulum.

The epicardium, sometimes included in descriptions of the myocardium as ‘epimyocardium’, is not present at the early stages of heart development (but see p. 1027).

**Endocardial cushions**

The extracellular matrix of the heart, historically termed cardiac jelly, promotes occlusion of the endocardial tubular lumen during myocardial contraction, thus providing mechanical assistance for the generation of the flow of blood. It also acts as a site for the deposition of inductive factors from the myocardial cells, which, in turn, modify the differentiation of specific endocardial cells. It has been called a gelatinoreticulum, a myoepicardial reticulum (Fig. 59.5C,D) and, more recently, the myocardial basement membrane. Here, the term cardiac extracellular matrix will be used. It is composed of, among other things, hyaluronic acid, hyaluronidase and fibronectin. Inductive signals originating from the myocardial cells cause a subset of endocardial cells lining the atrioventricular canal and the proximal outflow tract to transform into mesenchyme (cardiac mesenchyme); the endocardial cells in other regions of the heart tube, such as those in the ventricle, do not undergo such a transition. When activated by myocardial inductive factors, the endocardial cells lose their cell-to-cell associations, show decreased expression of neural cell adhesion molecule, and increased expression of substrate adhesion molecules such as chondroitin sulphate and fibronectin. They undergo rearrangement of their cytoskeleton necessary for migration, and they express type I procollagen. Uniquely, they retain their expression of endothelial markers. This epithelial to mesenchymal transition may, perhaps, be the only example of a mesenchymal population that is derived from an endothelial lineage.

Formation of cardiac mesenchymal cells at the atrioventricular canal and the proximal myocardial outflow tract is followed by their migration into the cardiac extracellular matrix. These cells proliferate between the endocardium and myocardium and, with local accumulation of extracellular matrix molecules, produce protrusions, termed endocardial or cardiac cushions, which bulge into the primary heart tube and initially provide the valvular mechanisms required in the atrioventricular canal and outflow tract. Their position corresponds to the future positions of the definitive cardiac valves. In the distal part of the outflow tract, which initially has myocardial walls, cells which are derived from the neural crest subsequently make significant contributions to the mesenchyme of the endocardial cushions. Although proper migration of these cells from the neural crest is crucial for normal development of the outflow tract and formation of the leaflets and sinuses of the arterial valves, their function is largely obscure. They are no longer found in the leaflets of the arterial valves in the formed heart, or in the muscular subpulmonary infundibulum, which is also derived from the outflow cushions. The endocardial cushions themselves ultimately fuse, forming a wedge of mesenchyme that serves to guide the union of the internal muscular septal structures (see p. 1024). At their time of fusion, the atrioventricular endocardial cushions are large relative to the size of the atrioventricular orifices; they will provide the scaffold for formation of the leaflets of the tricuspid and mitral valves.

**Cardiac myocytes – contraction, conduction and automaticity**
Cardiac myocytes share a number of characteristic features that distinguish them from other cells. All cardiac myocytes have sarcomeres and a sarcoplasmic reticulum and, in principle, share the capacity of producing an intrinsic cycle of electrical activity resulting in contraction. This phenomenon is called automaticity, or pacemaker activity. An absolute requirement for effective pacemaking is poor electrical coupling of the cells, which also implies slow conduction. It allows the cells to build up sufficient electrical charge which is then propagated through the surrounding myocardium. Thus ‘a small node can drive a large heart’ (see p. 1021).

Varying degrees of differentiation are seen in early populations of cardiac myocytes which can be categorized as forming working, nodal, conducting and primary myocardium (Table 59.1). Cells of the atrial and ventricular working myocardium display virtually no automaticity, but are well coupled and have well developed sarcomeres and sarcoplasmic reticular structures. The development of the synchronously (fast) contracting working myocardium requires fast conduction of the depolarizing impulse, and so the cells possess well-developed gap junctions. In marked contrast, the cells forming the nodes of the cardiac conduction system have the opposite phenotype, and resemble the myocytes which are found initially in the primary heart tube. The cells of the putative atrioventricular and peripheral ventricular conduction system have an ambiguous phenotype: the cells are well-coupled, thus allowing fast conduction of the depolarizing impulse, but otherwise retain an embryonic phenotype. The division does not imply that the cells belonging to one group are identical, but rather that they share distinguishing features developed to variable degrees.

Automaticity and slow conduction are features of the myocardium of the primary heart tube. The slow conduction of the depolarizing impulse over the heart tube causes a peristaltic wave of contraction, by means of which the blood is pushed towards the arterial pole. During the waves of contraction, the accumulated cardiac extracellular matrix closes the endocardial tube and prevents the backward flow of blood. Unambiguous morphologic markers are often lacking in the early embryonic heart, which means that it is not possible to distinguish the various cells phenotypically; automaticity and the speed of conduction have therefore become important functional parameters with which to describe the development of the different parts of the heart.
HEART TUBE

During the process of embryonic folding, the midline splanchnopleuric coelomic epithelium, which is derived from the primary heart field (cardiac crescent) becomes positioned ventral to the foregut. The splanchnopleuric epithelium is proliferative and gives rise to mesenchymal populations and particularly early cardiac myocytes which arise from the coelomic wall adjacent to the endoderm of the foregut (Fig. 59.5). After folding, the second heart field contributes cells to both the arterial and venous poles of the heart. It has been suggested that the secondary heart field may contribute cells only to those cardiac components that are required for the pulmonary circulation, namely the right ventricle and outflow tract at the arterial pole, and the atrial septum and the dorsal atrial wall at the venous pole. Extending this suggestion, the original primary heart-forming field would give rise to those components that are required for the systemic circulation, namely the systemic venous sinus and its tributaries, the initial atrium, the left ventricle, and the arterial conus, as seen in the outflow tract of primitive fishes, although this latter structure has no homologue in mammalian hearts.

During the process of folding, the pericardial cavity and concomitantly the myocardium, gradually extend around the forming endocardial tube, leaving the dorsal mesocardium, a transient connection that is analogous to the mesentery of the intestines (Fig. 59.5C,D). The persisting stalk of the dorsal mesocardium connects the venous pole of the heart with the splanchnopleuric mesenchyme around the developing lung buds and with the septum transversum mesenchyme, which will give rise to the liver. The dorsal mesocardium is the site of early mediastinal mesenchyme production. It disappears as a mesenteric entity during the third week of development, when the embryo has from 4 to 12 somites; at the same time, the endocardial heart tube becomes entirely surrounded by the myocardium, and enclosed within the pericardial cavity. The breakdown of the dorsal mesocardium establishes a passage across the pericardial cavity, from side to side dorsal to the heart, which persists as the transverse sinus of the pericardium.

At this stage, the heart is bilaterally symmetrical and has the form of an inverted ‘Y’. The legs of the Y are positioned caudal to each side of the cranial intestinal portal, where they form the venous pole of the heart (59.6A,B). The stem of the Y connects cranially with the great arteries, forming the arterial pole of the heart. From the outset, both poles are connected with the systemic vessels running from the embryo, the yolk sac, and the placenta. The pulmonary veins form later, during the fifth week of development, the initial venous primordium becoming evident in the mesenchyme derived from the dorsal mesocardium caudally. Also at this site, mediastinal myocardium continues to be added to the heart, forming the smooth dorsal wall of the left atrium, and providing the site of formation of the primary atrial septum.

Recent fate maps have shown that the primary heart tube contains cell lines which will contribute to only two compartments. The myocardium of the stem of the inverted Y contains only precursor cells of the left ventricle, and both legs of the inverted Y contain precursor cells of the atrioventricular canal and parts of both atrial chambers. There is no evidence to support the previous, traditional concept of heart development, i.e. that all the putative cardiac segments are already present in the straight heart tube and develop to contribute to the various parts of the definitive cardiac chambers. This hypothesis has now been disproved by elegant experimental studies which have shown that the definitive cardiac chambers are formed by local
differentiation and expansion, or ‘ballooning’, of the myocardial walls of the primary heart tube.

**Looping of the heart tube**

Cranial and caudal recruitment of myocardium and endocardium produces considerable lengthening of the primary heart tube. Recent studies of the mechanism of proliferation in the avian heart have shown that cardiac myocytes stop dividing after overt differentiation. The tube continues to elongate, largely as a result of the recruitment of additional myocytes to the tube, as shown by studies of both morphology and molecular lineages, and to a lesser extent because of an increase in the size of the myocytes which form the walls of the tube. The lengthening heart tube bends ventrally and rightwards, concomitant with the breakdown of the dorsal mesocardium. The bend is called the ventricular loop, since the left ventricle subsequently balloons and expands at its outer curvature, which is the original ventral side of the straight tube. The inner curvature of this loop was originally its dorsal side.

It is often stated that looping of the tube is the first visual evidence of asymmetry in the embryo, although careful examination reveals that the atrioventricular canal has become asymmetric prior to the start of looping. Although the sense of laterality of the developing organs of the body, including the atrial appendages, develops during gastrulation, the pathway of signalling that governs rightward looping of the heart tube remains unknown. However, it is now well established that signalling pathways including *Pitx2*, *nodal*, *lefty*, and *cited-2*, determine the formation of the morphologically left-sided or right-sided features seen in organs such as the lungs, the bronchial tree, the liver and spleen, and the atrial appendages.

By the time the primary heart tube has formed its ventricular loop, it is possible to distinguish the atrial and ventricular components of the developing heart (Figs 59.6D–G, 59.7A,B) and to recognize an outflow tract connected with the aortic sac and developing pharyngeal arch arteries. The cells which, at this stage, make up the outflow tract, will, at later stages, be found within the right ventricle. At the proximal side of the outflow tract, cells are recruited to the developing right ventricle and, contemporaneously, new cells are recruited to the outflow tract from the second heart-forming field. The atrial and ventricular components are separated one from another by the atrioventricular canal, which at this stage has significant length. The systemic venous tributaries drain directly to the atrial cavity.
Fig. 59.6 Local expansion of the myocardial wall of the early heart tube and heart tube looping. A, ventral view; B, ventral wall removed to show inner aspect of the early heart tube; C, left lateral view. The early heart tube is shaped like an inverted ‘Y’. The legs of the Y pass caudal to each side of the cranial intestinal portal. In the early heart tube the myocardium of the stem of the Y (purple) contains only precursor cells for the left ventricle. The remaining myocardium (grey) contains only precursor cells for the atrioventricular canal and atria. The precursor left ventricular cells expand first. D–G. Later heart tube showing looping. D, Ventral view. E, Ventral wall removed to show inner aspect of the folding heart tube. F, Left lateral view. G, Lateral wall removed to show the inner aspect of the heart from the left. In D and E the expansion of the right ventricle can be seen and the heart tube has elongated to the right. The developing atrium can be seen dorsolaterally in D–G.
The sinus venosus with right and left sinus horns, which forms at the confluence of the systemic venous tributaries, is a prominent structure in lower vertebrates. In mammals, it does not become recognizable as a morphologic entity until the systemic veins have excavated themselves from the mesenchyme of the body and been surrounded by myocardium. It then becomes incorporated into the pericardial cavity so that the sinus horns become part of the heart. All of these processes occur up to the 25th day of development in humans: only after this stage is it possible to consider development of the definitive atrial and ventricular chambers.
INFLOW TRACT

The working myocardium of the atrium differentiates locally at the dorsolateral sides of the heart tube (59.6D–G). The developing atrium then expands enormously, in dorsal, lateral and, most prominently, in a cranial direction. The cranial expansion is seen as pouches which become the left and right atrial appendages (Fig. 59.7A,B). The floor of the atrium, including the sinus venosus, and the atrioventricular canal, are made of primary myocardium. Less cellular proliferation occurs in these parts than in the expanding atrial chambers: the primary myocardium marks the inflow to, and the outflow from, the initial atrial chambers as ‘rings’ which are also associated with the formation of the conduction system (see p. 1021). The ring at the inflow defines the sinu-atrial junction, whilst the atrioventricular canal, which forms the atrial outlet during development, will eventually be incorporated into the definitive right and left atrial chambers as the atrial vestibules. Although it is possible to recognize the forming left and right atrial appendages at this stage, the right being more extensive than the left, the atrium itself has a single cavity and there is no evidence of septum formation. The myocardium of the sinus venosus and the newly forming mediastinal myocardium are smooth-walled, whereas the myocardium of the appendages shows ridges, the pectinate muscles, on the inner surface. The formation of the different appendages is under control of the Pitx2 signalling pathway. The myocardium of the appendages has a chamber phenotype, or is working myocardium; it expresses atrial natriuretic factor and connexin40 among other markers.

Right atrium

The further development of the right atrium is characterized by the incorporation of the sinus venosus into the right part of the primary atrium. This process is under control of the T-box transcription factor Tbx18. At about 4 weeks of development, the sinuatrial junction of the looping primary heart tube is positioned symmetrically in the midline (Fig. 59.8; see also Figs 13.1B, 73.8). The left and right common cardinal veins drain directly into the cavity of the primary atrium. The atrial myocardium extends to the margins of the pericardial cavity, and strictly speaking the sinus venosus is not yet formed, because the systemic venous tributaries are embedded within the mesenchyme of the septum transversum.
The changes to the sinus venosus. A. Dorsal view of the early heart tube shown in Fig. 59.6D. Changes in the circulation bring the venous circulation to the right. This causes enlargement of the right horn of the sinus venosus, atrium and attenuation of the left horn of the sinus venosus. C. The right horn of the sinus venosus becomes absorbed into the atrium. The left horn of the sinus venosus becomes the coronary sinus. D. Dorsal view of the embryonic heart showing the relative changes to the sinus venosus.

During subsequent development, the pericardial cavity expands to enclose the terminal segments of the systemic venous tributaries, and at the same time their walls differentiate as myocardium. They can now be termed the left and right horns of the sinus venosus; each horn receives the union of the corresponding umbilical vein, vitelline radicles, and common cardinal vein (Fig. 59.8; see also Fig. 73.8). Concomitantly, the constriction between the left horn and the atrium becomes more pronounced. As the dorsal wall of the left atrium is formed from additions of mediastinal myocardium, the left horn becomes incorporated into the developing left atrioventricular junction, its orifice draining to the newly formed right atrium. At the same time, the left-sided venous tributaries diminish in size; the left common cardinal vein forms the oblique vein of the left atrium, and the left sinus horn forms the coronary sinus (Fig. 59.8), maintaining its own myocardial wall as it becomes incorporated into the atrioventricular junction.

The right sinus horn increases rapidly in size with growth of the liver (see Figs 73.8, 73.9). The vitello-umbilical blood flow enters the right horn through a wide but short hepatocardiac channel, which becomes the cranial end of the inferior vena cava. The right horn also receives the right common cardinal vein, draining the blood from the right side of the body (Fig. 59.8B,C). Later, when transverse connections are established between the cardinal veins, the blood from the left side of the body also reaches the heart via the veins draining the right side (see Fig. 13.4). As these changes take place, the right sinus horn, including the proximal parts of the superior and inferior cardinal veins, becomes incorporated into the right atrium, forming the smooth-walled systemic venous sinus, also known as the sinus venarum.

The right sinus horn opens into the right atrium through its dorsal and caudal walls (Fig. 59.8; see Fig. 59.12). The sinuatrial orifice becomes elongated and slit-like, guarded by two muscular folds, the left and right sinuatrial (venous) valves. These two valves meet cranially and become continuous with a fold that projects from the atrial roof, the septum spurium. The valves also meet caudally, and merge with the inferior
atrioventricular cushion. With ongoing development, the cranial part of the right sino-atrial valve loses its fold-like form, but its position is indicated in the adult heart by the site of the crista terminalis of the right atrium. Its caudal part forms the valve of the coronary sinus, also known as the Thebesian valve, and most of the valve of the inferior vena cava (Eustachian valve). The union of the two valvular remnants then passes through the tissue which separates the orifice of the coronary sinus from the fossa ovalis. This area is known as the 'sinus septum', but in reality this 'septum' is no more than a muscular fold in the dorsal wall of the right atrium. The continuation of the venous valves persists as the tendon of Todaro, an important landmark to the location of the atrioventricular node in the definitive heart. The left venous valve blends with the right side of the atrial septum; there is usually no trace of it in the postnatal heart.
Three representative stages in the development of the atrial septum. 

**Fig. 59.12**

A–C, Coronal views from the front; D–F, lateral views from the right side. 

A and D, The septum primum has not yet obliterated the original communication between the two atria (foramen primum) and the atrioventricular endocardial cushions have not yet fused. 

B and E, The atrioventricular endocardial cushions have fused with each other and with the septum primum, which has broken down in its dorsal part to form the foramen secundum. 

C and F, The septum secundum is forming on the right side of the foramen secundum from an interatrial fold.

**Left atrium**

Following the formation of the primary atrium and the left atrial appendage, the left atrium takes shape by the formation and incorporation of mediastinal myocardium. While the tributaries of the sinus venosus approach the atrium caudally, the differentiating pulmonary veins gain their entrance to the atrial cavity through the dorsal mesocardium (Fig. 59.5). The topographical relationships seen in the postnatal heart are thus established as soon as differentiation of the pulmonary venous portal occurs.

Early in the development of the atrium, the pulmonary vein develops as a solitary channel from angiogenic cells derived from the dorsal mesocardium, and establishes continuity with the vascular plexus formed in the mediastinal mesenchyme around the developing lung buds. The solitary pulmonary vein opens into the caudo-dorsal wall of the atrium adjacent to the developing atrioventricular junction, its atrial orifice being flanked by two prominent ridges. The primary atrial septum develops from the right ridge, following incorporation of the left sinus horn into the right side of the primary atrium, thus confining the pulmonary venous orifice to the developing left atrium (Fig. 59.12). The pulmonary vein initially branches within the dorsal mediastinal mesenchyme, its tributaries draining blood from the developing lung. With continuing development, the walls of the venous channels become surrounded by myocardium, this process occurring to the level of the second bifurcation. The veins then expand, and are incorporated into the roof of the left atrium, eventually forming the greater part of its cavity. However, all four pulmonary veins do not achieve their separate opening into the atrial roof until well after the completion of atrial septation, and probably not until the 10th or 11th week of development. Variations in the precise pattern of pulmonary venous drainage are quite common. With these changes, the left half of the primary atrium becomes progressively restricted to the mature appendage. The myocardial sleeves surrounding the pulmonary orifices taper off, and become intermingled with fibrous tissue. In later life, it is likely that this intermingling of myocardial and fibrous tissues forms the substrate for some forms of atrial fibrillation. The opening of the solitary pulmonary vein to the left of the right pulmonary ridge is an essential pre-requisite for atrial septation.
VENTRICLES

The ventricles develop at the ventral side of the looping primary heart tube during the fourth week of development (Figs 59.6, 59.7). The left ventricle develops from the stem of the Y-shaped heart, the right ventricle develops later, downstream relative to the left ventricle, when more myocardium has been added to the cardiac tube. As a result of the looping of the heart tube, the right ventricle is positioned at the right of the left ventricle, which is a prerequisite for the appropriate connection with the expanding atrial component of the heart. Unlike the atrial chambers, the morphological differences between the right and left ventricles are not part of the general asymmetry between the right- and left-sided organs of the body, but rather are under control of the signalling pathways which determine caudo-cranial differentiation. Retinoic acid, and its downstream transcription factor Tbx5, play a crucial role in this process.

The myocardium at the inner curvature, the original dorsal side of the cardiac tube, remains smooth-walled and maintains its molecular phenotype, whereas the myocardium at the outer curvature of the myocardial tube displays trabeculations in the fifth week of development (Fig. 59.7B). By stage 17, the trabeculations have achieved a typical spatial orientation, giving a sponge-like appearance to the internal aspect of both ventricles (Fig. 59.9). The definitive trabeculations, coarse in the right ventricle but much finer in the left, are first observed about the 40th day of gestation: they appear initially in the walls of both ventricles at the level of the atrioventricular junction and develop towards the apex of the heart. By the time the fetus is 10 weeks old, the trabeculations are much sparser, and are confined to the apical regions. This process of remodeling is accomplished without the intervention of macrophages or inflammatory cells in the immediate interstitium. The ventricular myocardium, encompassing the trabeculations and exterior wall, possesses a chamber phenotype, the myocytes expressing, among other proteins, the gap-junctional protein Cx40 and atrial natriuretic peptide. This myocardium stops proliferating and differentiates into the fast-conducting peripheral ventricular conduction system, whereas the outer layer becomes highly proliferative and forms the compact layer of the ventricular wall.
Fig. 59.9: SEM of human heart at 42 days gestation. The right lateral wall of the right atrium, right ventricle and the outflow tract have been removed. The valve of the sinus venosus (V) is prominent. There is no septal cusp of the tricuspid valve guarding the inlet portion of the right ventricle. The parietal cusp is well developed. The valve of the foramen ovale is intact. Note the adjacent right lateral tubercles (O). A small interventricular foramen ovale is present (small arrowhead). There is a well developed right ventricular outlet tract (curved arrow). E, embryonic trabeculae; P, pulmonary trunk; V, pulmonary valve.
Initially the outflow tract possesses myocardial walls up to the pericardial reflections. It displays a characteristic bend, which has a proximal part arising from the developing right ventricle and a distal part which becomes continuous with the aortic sac beyond the pericardial reflections. Although this bend is a conspicuous morphologic feature, it is highly unlikely that the cells to either side of it retain their position during subsequent development. Instead, it seems probable that cells are recruited from the second heart-forming field, and pass through the outflow tract to contribute to the definitive right ventricle. Subsequently, still more cells are recruited from pharyngeal mesenchyme, passing proximal to the pericardial reflections and forming the intrapericardial components of the arterial trunks. There remains much disagreement as to how best to describe these morphological parts of the outflow tract. Some authors have labeled the proximal myocardial part the conus, calling the distal part the truncus, and the intrapericardial portion of the outflow tract the aortic sac. Others have called the entire myocardial outflow tract the bulbus, since the myocardial outflow tract of primitive vertebrates, called the conus arteriosus in primitive fish, and the bulbus cordis in amphibia, is presumed to develop into the right ventricle in higher vertebrates. Because the terms conus and truncus have been inconsistently used in literature, we prefer simply to describe proximal and distal parts of the myocardial outflow tract, and to describe, when it appears, an intrapericardial arterial portion of the outflow tract, this part interposing between the muscular component and the ventral aorta, the distal junction occurring at the pericardial reflections.

Given that different authors use different terminologies, it is not surprising that formation of the outflow tract remains one of the most confusing areas of cardiac development. The recent finding that the stem of the heart tube contains precursor cells exclusively for the left ventricle makes it essential to adopt descriptions which follow dynamic events, rather than continuing to use static names. Thus, as soon as the primary heart tube bends to produce its ventral ventricular expansion, by definition the developing ventricle achieves inlet and outlet components, even though these structures are not the definitive ventricular inlets and outlets. Cells that, initially, are found in the ventricular outflow tract subsequently become cells of the right ventricle. Furthermore, working myocytes can easily be distinguished from the primary myocytes of the straight heart tube. The primary myocardium is smooth-walled, whereas the developing myocardium of the ventricles is trabeculated, and expresses specific markers such as atrial natriuretic peptide and connexin40. Thus, that part of the primary heart tube downstream of the developing ventricular loop is termed the outflow tract, irrespective of the fact that eventually it will largely become incorporated within the definitive right ventricle (Figs 59.6, 59.7). Moreover, within the inner curvature of the
ventricular loop, the walls of the outflow tract and atroventricular canal fade into one another without a clear boundary. Indeed, ventricular working myocardium never develops at the inner curvature. It is within this ventricular part of the primary heart tube that the cushions of the atroventricular canal and the outflow tract must achieve appropriate connections with the muscular ventricular septum in order to divide this part of the tube into left and right compartments. The cavity of the tube within which these events take place has been called ‘interventricular foramen’. This is incorrect, since it is rather the region between adjacent parts of the primary heart tube. It is, nonetheless, the remodelling of this inner curvature that sets the scene for the completion of cardiac septation.
CARDIAC FUNCTION AND THE CONDUCTION SYSTEM

Although only mammalian hearts have a well-defined conduction system, an essentially similar electrocardiogram can be recorded from animals as diverse as fish and man, indicating that the electrical connections between the cardiac components have been conserved during vertebrate evolution. Indeed, the development of the conduction system of the heart is inextricably associated with the development of the basic building plan for the heart. The conduction system is best defined as the system that initiates and conducts the sinus impulse. In mammals, it encompasses the sinus-atrial node, the atrioventricular node, the atrioventricular bundle, the bundle branches and their terminal ramifications. The nodes and the atrioventricular bundle can be considered the central conduction system, while the bundle branches and their ramifications represent the peripheral ventricular conduction system. The sinus impulse is generated in the sinus node, whence it is rapidly propagated through the atrial myocardium towards the atrioventricular node, where propagation is delayed. After an essential period of atrioventricular delay, the impulse travels rapidly through the atrioventricular conduction axis and the peripheral ramifications to reach the ventricular myocardium, which is then rapidly depolarized. Following repolarization, the sequence recurs in endless fashion throughout the life of the individual. The term ‘conduction system’, as opposed to the working myocardium of the chambers, may suggest that the working myocardium does not conduct, while the conduction system conducts rapidly. In order to produce powerful synchronous contractions, the working myocardium of the chambers must also, of necessity, conduct rapidly, whereas to act as a pacemaker, the cells of the nodes need to be poorly coupled, and hence display slow conduction.

The vertebrate heart is myogenic, implying that all cardiomyocytes have the capacity to generate and conduct the depolarizing impulse. Because cardiac myocytes are electrically coupled, the cells with the highest pacemaking activity take the lead. In the formed normal heart, the leading pacemaker is always within the sinus node. In embryonic hearts, the leading pacemaker is always found at the venous pole. Thus, it is the most recently recruited cells at the venous pole which always have the highest pacemaking activity. All regions of the early embryonic heart tube possess poorly coupled cells and display intrinsic automaticity, thus permitting slow propagation of the depolarizing impulses along the cardiac tube, and producing matching peristaltic waves of contraction which push the blood in an antegrade direction. The myocytes of a developing heart do not have well-developed sarcomeric structures, and have a poorly developed sarcoplasmic reticulum. This tissue has been called primary myocardium, distinguishing it from the rapidly conducting and well-developed working myocardium of the atrial and ventricular chambers.

As development proceeds, the ventricular chambers develop in the cranial part of the heart tube, by ventral expansion, and the atrial chambers in the caudal part by dorso-lateral expansion (Fig. 59.6). An adult type of electrocardiogram can be recorded from such hearts, showing rapid atrial depolarization, a period of atrioventricular delay, and rapid ventricular depolarization. The electrocardiographic tracings reflect the development of fast-conducting components within a slowly conducting heart tube, i.e. the development of a morphologic conduction system. The newly developed working myocardium expresses atrial natriuretic factor, along with the gap junctional proteins connexin40 and 43, which permit fast conduction.
Like the early peristaltic heart, flow through the developing chambered heart remains directional because the dominant pacemaking activity is still at the inlet of the heart. Peristaltic hearts do not need valves, whereas chambered hearts require the presence of one-way valves at the inlets to, and the outlets from, the chambers. The slowly conducting atrioventricular canal, interposed between the atrium and the ventricle, and the outflow tract positioned between the ventricle and the great arteries, are the parts which contain the endocardial cushions. These are able to function as sphincteric valves, as a result of their prolonged duration of contraction. These components retain their function until the definitive leaflets of the one-way valves have been sculpted from the cushions. The primary myocardium of the outflow tract does not regress until the arterial valves have been formed, and does not disappear in its entirety until around the twelfth week of human development. The primary myocardium of the atrioventricular canal is eventually incorporated into the atrial vestibules at the same time as the formation of the atrioventricular valves, becoming sequestered on the atrial side of the atrioventricular junctions between 6 and 12 weeks of development (Fig. 59.10). An important part of the canal persists dorsally, where it differentiates into the slowly conducting atrioventricular node.

Considerable progress has been made over recent years in deciphering the pathways involved in establishing the building plan of the heart (Fig. 59.11). The combined action of the transcription factors Tbx5 and Nkx2–5 is required for the formation of the myocardium of the atrial and ventricular chambers. Tbx5 is expressed in a gradient over the heart tube, decreasing in concentration from caudal to cranial and may impose positional information. However, its pattern cannot explain the localized formation of the chambers and the conduction system. Localized expression of the transcriptional repressors Tbx2 and Tbx3 in the inflow tract, the floor of the atrium, the atrioventricular canal, the inner curvature of the ventricular region, and the outflow tract prevents the differentiation of primary into working myocardium. Tbx2 and Tbx3
effectively compete for binding to the promoters of the chamberspecific genes, such as atrial natriuretic factor and connexin40. The remaining primary myocardium of these regions initially induces the endocardium to undergo epithelial-to-mesenchymal transition, by which process the cardiac cushions become filled with mesenchyme. The myocardium also participates in the alignment of the atrial and ventricular chambers (which is essential for proper cardiac septation, and which is guided by the fusing cardiac cushions), and it forms the conduction system, including the sinus and atrioventricular nodes, the atrioventricular bundle, the floor of the developing right atrium (the internodal region), and the entirety of the atrioventricular canal. In the early chamber-forming heart of the mouse, Tbx3 is expressed in the atrioventricular canal, the floor of the atrium and around the orifices of the systemic venous tributaries, but not in the dorsal mesocardium surrounding the entrance of the pulmonary vein. During subsequent development, the domain of expression of Tbx3 expands from the atrioventricular canal to form a crescent on the crest of the ventricular septum. The dorsal aspect of this crescent develops into the atrioventricular bundle, while the atrioventricular node is formed at the dorsal junction with the atrioventricular canal. The ventral parts subsequently disappear during development.
The fact that the ventricular conducting system originates from a single primary ring provides a solid base for understanding the disposition of the conducting system in a number of congenital malformations. The concept accounts particularly well for the morphology and disposition of the atrioventricular node and bundle in hearts with straddling tricuspid valves, with double inlet left ventricles, and with congenitally corrected transposition.
SEPTATION OF THE EMBRYONIC CARDIAC COMPARTMENTS

The flow of blood on the right and left sides does not intermingle even in the developing heart, because flow is laminar, and the pressures are similar at the right and left sides. It is only after birth that the pressures in the ‘left’ systemic circulation become higher than those in the ‘right’ pulmonary circulation, and therefore the different flows have to be separated physically in order to prevent admixture of oxygenated and deoxygenated blood. Prior to birth the lungs are not functioning and blood flow to them is small. Even so, normal development of the heart requires that all cardiac compartments receive an adequate amount of blood. To this end, even before birth, the systemic blood of the right atrium is guided to the left atrium so that the left half of the heart and the brain is provided with a normal flow of blood. The right ventricle, in contrast, drains to the dorsal aorta via the ductus arteriosus (see Fig. 35.8). The walls that separate the right and left sides of the heart are largely formed in the fourth and fifth week of development. Some time later, not only the components of the primary heart tube, specifically the atrioventricular canal and the outflow tract, but also the atrial and ventricular chambers, must be separated physically into right and left halves. However, each compartment is separated in markedly different fashion.

Septation of the atrial chambers

As a prelude to atrial septation, the right horn of the sinus venosus is incorporated into the right part of the atrium and the pulmonary vein arises as a midline structure within the dorsal mesocardium. Internal separation into right and left atria is mainly effected by growth of two septa coupled with remodelling of the venous compartments. At the end of the fourth week of development, a crescentic fold, the primary atrial septum or septum primum, grows by active proliferation from the dorso-cranial atrial roof into the direction of the atrioventricular canal, extending downwards just to the right of the entrance of the pulmonary vein (Fig. 59.12A,D). It is separated from the left sinu-atrial valve by the interseptovalvular space. The leading edge of the septum primum is covered by a mesenchymal cap in continuity dorsally with extracardiac mesenchyme (mediastinal mesenchyme) derived from the dorsal mesocardium which forms the vestibular spine, or spina vestibuli. The ventral horn of the septum primum reaches the ventral (cranial) atrioventricular cushion, while the dorsal horn reaches the dorsal (caudal) cushion. Thus the primary atrial foramen, the foramen or ostium primum, is entirely surrounded by mesenchyme derived from endocardium. Ventral and caudal to the advancing edge of the septum primum, the developing atrial chambers communicate through the foramen primum (Fig. 59.12A,D).

As the foramen primum diminishes in size, the upper margin of the septum primum perforates by apoptosis, and thus right to left shunting of blood continues through a secondary foramen, the foramen or ostium secundum. The latter is formed before the end of the fifth week of development. Initially it lacks an upper rim, since its upper border is the atrial roof. The foramen primum is finally occluded in the median plane, as the edge of the septum primum merges with the fusing atrioventricular cushions (Fig. 59.12B,E). The foramen secundum then enlarges to permit free passage of blood from the right to the left atrium.

The solitary opening of the pulmonary vein into the roof of the left atrium, which is originally adjacent to the atrioventricular junction, becomes incorporated into the atrial wall, ultimately forming four separate orifices at the corners of the atrial roof. As this
development continues, the muscular atrial roof itself invaginates on the right side of the primary atrial septum (Fig. 59.12B,E), the invaginated fold constituting the septum secundum. The free edge of the septum secundum overlaps the foramen secundum. When left atrial pressure exceeds right atrial pressure in postnatal life, the septum primum closes against the septum secundum as a flap-valve (Fig. 59.12C,F). The passage taken by blood as it passes from the right atrium, under the crescentic edge of the septum secundum, then obliquely towards and through the foramen secundum to the left atrium, persists throughout intrauterine life as the foramen ovale. At first, the foramen ovale is sited cranio-dorsally relative to the atrial septum, but with remoulding of the venous components, it achieves a cranio-ventral position.

**Septation and appropriate positioning of the atrioventricular canal**

Extracellular matrix accumulates between the endocardium and myocardium of the primary heart tube. However, it mostly disappears in the regions of ballooning of the chamber myocardium of the developing atria and ventricles. The matrix becomes filled with mesenchyme in the persisting regions of the primary heart tube. In conventional accounts of the process, these regions are called the atrioventricular canal and the outflow tract, or conotruncus. The dorsal or inferior atrioventricular cushion continues into the floor of the atrium, which is made of primary myocardium. As the cushion extends dorsally, it meets the mediastinal mesenchyme in the region initially termed the spina vestibuli, where it continues as a mesenchymal cap running along the leading edge of the septum primum until it meets the ventral, or cranial, atrioventricular cushion (Fig. 59.12 and see Fig. 59.14). The dorsal cushion also has a significant ventricular extension in the inner curvature of the heart tube, which comes to lie on top of the developing muscular ventricular septum. The two atrioventricular cushions fuse in the sixth week of development, dividing the atrioventricular canal into its right and left components. The cushions are very large relative to the canal, leaving narrow right and left slits, which increase markedly in size during further development.

![Fig. 59.14](image.png)  
**Fig. 59.14** Septation of ventricles and outflow tract. **A**, Frontal view of heart at stage 13 with the outflow tract reflected to the right. Lines show the level of transverse sections of the atrioventricular cushions and outflow tract. Note that blood from both atria pass through the embryonic interventricular foramen at this stage. **B**, Sagittal section of heart along the dotted line in A showing the atrioventricular junctional region seen from the right side. The atrioventricular cushions extend onto the leading edge of the septum primum (although the mesenchymal cap on the atrial septum, see Fig. 59.12, probably has a different developmental origin).

At the start of stage 10, the venous pole, the atrioventricular canal, the developing left
ventricle and the outflow tract are all positioned symmetrically around the midline (Fig. 59.13A). As a result of the subsequent rapid growth of the cardiac tube, the atrioventricular canal moves in its entirety to the left (Fig. 59.13B), as the ventricular part of the heart tube loops to the right, thus placing the developing left ventricle on the left, and the forming right ventricle on the right (Fig. 59.7). This ventricular loop is conspicuous throughout the fourth and fifth weeks of development, and it is at this stage that a deep interventricular groove appears externally. Over this period the atrial floor, including the developing systemic venous sinus (sinus venosus) and the atrioventricular canal, move to the right (Fig. 59.13C). The developing pulmonary vein remains anchored in the midline and, subsequent to these manoeuvres, the atrioventricular canal once more becomes positioned in the midline: this process facilitates the appropriate connections of the developing muscular septum with the atrioventricular and outflow cushions. The orifice of the sinus venosus is by now positioned to the right. From the outset, the muscular ventricular septum develops in line with the right side of the dorsal (inferior) atrioventricular cushion (Fig. 59.14), so that the separating right atrium always has direct access to the developing right ventricle. The process also ensures that space remains ventrally for incorporation of the subaortic component of the outflow tract into the left ventricle.
Septation of the ventricles

After the looping of the heart tube, it is easy to gain the impression that the atrioventricular canal communicates exclusively with the developing left ventricle, while the outflow tract is supported exclusively by the developing right ventricle. In the definitive heart, blood entering the right ventricle passes in through the right atrial vestibule and exits through the muscular subpulmonary infundibulum, while blood entering the left ventricle passes in through the left atrial vestibule, and exits through the aortic root. The changes needed to produce the definitive connections between the cardiac components are complex. Three distinct structures contribute to the formation of the postnatal ventricular septum: the muscular ventricular septum, the proximal parts of the outflow cushions and the atrioventricular endocardial cushions.
The latter two components separate those parts of the primary heart tube that are committed to the right and left ventricles, as opposed to the ballooned apical ventricular components. Inappropriate formation and connection of the cushions with the muscular ventricular septum underscores deficiencies of the definitive ventricular septum; such lesions account for about two-thirds of all cardiac septal defects.

Separation between the right and left ventricles is initially heralded by the appearance of a caudal crescentic ridge within the ventricular loop. The trabeculated parts of the ventricles contain less extracellular matrix than the walls of the primary heart tube, and it is these parts of the chambers that expand on each side of the ridge that remains between them. The crest of the developing septum, therefore, is its oldest portion. The more apical parts are added concomitant with enlargement of the chambers, as if they were expanding like balloons. The impression can be gained that the dorsal and ventral horns of the ventricular septum grow along the ventricular walls, meeting and fusing with the right extremities of the dorsal and ventral cushions of the atrioventricular canal. In reality, the crest of the septum marks the position of the original primary heart tube, and becomes the atrioventricular bundle. The septum has a free sickle-shaped margin that, together with the fused caudal surface of the endocardial cushions, bounds an ovoid foramen. Previously this foramen has erroneously been termed the interventricular, or bulboventricular foramen: it is no more than a locus within the cavity of the primary heart tube. The apical trabecular components of the ventricles balloon from the ventral side of the primary heart tube. At the dorsal side, or the inner curvature, there is no chamber myocardium, only the smooth walls of the primary heart tube. Therefore, from the outset of the process, the forming apical parts of the ventricles are separated by a muscular septum. The foramen marked caudally by the crest of the ventricular septum provides the initial inlet to the developing right ventricle, and the outlet for the developing left ventricle. Completion of ventricular septation requires division of this primary foramen, rather than its closure. It also demands appropriate connection between the muscular septum and the divided atrioventricular canal, including its cushions, and with the divided outflow tract, along with its cushions (Fig 59.14).

Use of inappropriate terminology means that the entire region upstream relative to the foramen has previously been called the primitive ventricle, the entire downstream region the bulbus, and the junction between them, the bulboventricular junction. In the account presented here, the area is termed the primary junction, initially marked by a distinct notch on the outside of the heart, and inside by the corresponding ridge of the developing ventricular septum. The ridge is positioned between the atrioventricular orifice, which is initially a common structure, and the caudal part of the forming right ventricle.

Appropriate connection with the separating atrioventricular and arterial junctions is essential for the development of a four-chambered heart. The serendipitous discovery of the expression of a 'neural' antigen in the primary junctional myocardium, surrounding the so-called primary interventricular foramen, has clarified the steps involved in the remodeling of this region at the inner curvature.

**Septation and appropriate positioning of the outflow tract**

The length of the myocardial portion of the outflow tract decreases markedly between the fourth and eighth weeks of development. In part, the myocardium becomes
incorporated into the ventricles, and in part it disappears by apoptosis: in the definitive heart, there is no distinct myocardial outflow tract present within the left ventricle, because the myocardium which initially separated the developing mitral and aortic valves disappears, leaving the fibrous aortic-mitral continuity distinctive for the postnatal heart. In the right ventricle, the proximal myocardial outflow tract persists as the smooth-walled muscular subpulmonary infundibulum. Formation of the part adjacent to the aortic root requires muscularization of the most proximal parts of the outflow cushions to form the greater part of the supraventricular crest, or crista supraventricularis.

Key to separation of the outflow tract is the appearance of the two outflow ridges, or cushions, which spiral one round another as they run from the distal end of the right ventricle, where they are positioned septally and parietally, to the aortic sac (Figs 59.14, 59.15). Within the aortic sac, a transverse wedge of tissue, termed the aorto-pulmonary septum, separates the origins of the arteries traversing the fourth and sixth pharyngeal arteries. The septum is formed from dorsal mediastinal mesenchyme. Myocardial precursor cells and non-myocardial cells are added to the outflow tract, the latter forming the intra-pericardial components of the arterial trunks. Neural crest cells migrate from the pharyngeal mediastinal myocardium into the outflow cushions. They do not appear to populate the septum itself, but form the larger parts of the walls of the intrapericardial portions of the truncus arteriosus. The precise relationship between the outflow cushions and the newly formed aortic arch arteries, which never possess a septum between them, has still to be assessed.

Fig. 59.15 Septation of outflow tract. A, SEM of human heart at stage 18. The pulmonary trunk is separate from the aorta. B, SEM of human heart at stage 17 showing the luminal aspect of the right ventricle and the outflow tract. The anterior and parietal wall of the outflow tract has been removed along the dotted lines shown in A. C, SEM with added colour to show the structures in B. The outflow cushions are unfused; the distal margins of both outflow tract cushions are contributing to the developing pulmonary valve, the third leaflet and sinus of this valve are derived from the intercalated cushion. The components of the aortic valve develop from the dorsal aspect of the outflow tract cushions.

(By courtesy of Prof G Steding, Göttingen, with permission from Oostra RJ, Steding G, Lamers WH, Moorman AFM. Steding's and Virágh's scanning electron microscopy
The spiral outflow ridges start to fuse from the sixth week onward, initially in the distal part of the outflow tract, and fusions continue gradually in the direction of the ventricular septum (Figs 59.15, 59.16A). The most proximal parts of the cushions remain unfused when the aorta and pulmonary trunk have gained their separate existence within the pericardial cavity. At this time, the proximal part of the outflow tract, upstream to the intrapericardial arterial trunks, remains encased in a myocardial sleeve. The arterial valves and sinuses then develop within the more distal part of this myocardial outflow tract; the outer myocardial wall does not disappear completely until well after the completion of septation. The most proximal parts of the cushions are the last ones to fuse, and they then muscularize and join the muscular ventricular septum, thereby joining the aorta into the left ventricle. The dorsal atrioventricular cushion maintains its mesenchymal character, becoming the membranous part of the interventricular septum in the formed heart. Formation of its interventricular and atrioventricular components does not become evident until the septal leaflet of the tricuspid valve delaminates from the surface of the ventricular septum.
Fig. 59.16  **A**, SEM of human heart at 32 days (stage 15). The right lateral wall of the right atrium, right ventricle and the outflow tract have been removed. The septum primum (S) and the developing valve of the sinus venosus (white arrow) are at a distance from the unfused ventral (V) and dorsal (D) atrioventricular cushions. The interventricular foramen (primum) is open (O). Its lower margin is made up by the developing interventricular septum (I). Note the left anterolateral ridge (R) and, at the distal margins of the truncus arteriosus, the valve swellings (*) of the putative aorta and pulmonary trunk. IV, origin of IVth aortic arch; VI, origin of VIth aortic arch. At, atrium; E, embryonic trabeculae. **B**, Septal aspect of the right ventricle of a human heart at 8 weeks. Delamination of the septal cusp of the tricuspid valve (T) is taking place. A cleft (black arrow) has appeared, marking the posterior margin of the septal cusp. There are no clefts delineating the anterior margins in the region adjacent to the supraventricular crest (C), and the endocardium is continuous. No tension apparatus is present. AV, aortic valve; LA, left atrium; PV, pulmonary valve; RA, right atrium.
NON-MYOCARDIAL COMPONENTS OF THE HEART

The non-myocardial components of the heart are the epicardium, including the coronary vasculature, and the interstitial fibroblasts and the valvular apparatus, which are formed in their larger part from endocardially derived mesenchyme. From the outset, the atrioventricular valves, mitral and tricuspid, are formed at the site of the initial atrioventricular canal, whereas the aortic and pulmonary valves are initially developed within the myocardial outflow tract, and only later achieve the semilunar attachments of the leaflets, which cross the anatomic ventriculo-arterial junctions. All of the leaflets form initially as internal endocardial projections which enclose a myocardial basement membrane, matrix, and mesenchymal cells. The precise mechanisms involved in the formation of these areas have still to be determined.

Development of the epicardium and the coronary vasculature

The epicardium, coronary vascular bed, and interstitial fibroblasts develop from a mesothelially covered protrusion of mesenchymal cells, the pro-epicardium, which arises from the pericardium in the region of the sinus venosus during week 5. The base of the pro-epicardium encompasses bi-potential pericardial cells which are recruited either to the cardiac lineage to form the venous pole of the heart, or else to the epicardial lineage. Bone morphogenetic proteins and fibroblast growth factors influence which lineage is followed; the precise mechanism of specification is not yet clear. Cells detach from the pro-epicardium and spread over the myocardial tube from caudally to cranially, and from dorsally to ventrally. Thus, in successive stages, the pro-epicardial cells approach the myocardial surface of the developing atria, atrioventricular canal, ventricles, and the proximal part of the outflow tract. The distal part of the outflow tract, as it becomes arterialized with regression of the initial myocardial walls, is covered by an outgrowth of the pericardial mesothelium at the site of the initial pericardial reflections. After the formation of the epicardium, a space is formed between the developing epicardium and the outer myocardial layer, which is particularly pronounced at the atrioventricular and outflow regions of the heart tube. This is the subepicardial space, or subepicardium: it is subsequently populated by mesenchymal cells which are largely derived from the epicardium and which play an important role in the formation of the coronary vasculature. The precursors of coronary fibroblasts, smooth muscle cells and endothelium are all derived from these pluripotent cells, which possibly also play roles in the development of non-vascular tissues, including the mesenchyme of the atrioventricular cushions and some myocardial elements. The remnants of the pro-epicardium can be found in the area of the developing systemic venous tributaries up to stage 15.

The coronary arteries were previously assumed to form by means of
angiogenesis, or sprouting from the aortic root. However, recent studies have demonstrated that the vessels develop prior to the formation of the arterial orifices in the aortic sinuses: it is now thought that the vessels arise by vasculogenesis, and that mesenchymal cells in the subepicardial space give rise to primitive vessels which invade the myocardium and spread over the myocardial surface. Sprouts of this plexus approach the base of the outflow tract, and connect to the sinuses of the aortic root. Ultimately only solitary right and left coronary arteries remain, although in up to one-third of human hearts small accessory branches of the coronary arteries take origin directly from the coronary sinuses. The vessels that remain acquire a medial wall and an adventitial covering, whereas those that do not form a medial wall are destined to regress. The coronary veins develop in a similar manner from a plexus of capillaries which sprouts subepicardially; they empty into the coronary sinus and directly to the atrial chambers. The mature coronary vascular pattern is established by remodeling of the capillary plexuses, and reduction in the number of arteriovenous anastomoses.

**Atrioventricular valves**

Initially, the atrial myocardium is continuous with the ventricular myocardium through the myocardium of the atrioventricular canal. The atrioventricular canal itself is characterized by the tissues of the atrioventricular groove on the epicardial side, and of the endocardial cushions on the endocardial side. As the atrioventricular valves develop, these tissues fuse at the ventricular margin of the canal, and so disrupt myocardial continuity. Molecular lineage studies in mouse have demonstrated that the valvular leaflets and their tendinous cords are subsequently derived in their entirety from the endocardium.

The atrioventricular valves develop as shelf-like projections from the margins of the atrioventricular orifices. They are directed as almost complete conical sheets towards the ventricles, their advancing edges continuing, initially as trabecular ridges, deep into the ventricular cavity. With continued differential growth and excavation on their ventricular aspects, each sheet develops major indentations forming the mitral and tricuspid orifices and defining their principal leaflets. Minor marginal indentations subdivide some leaflets into scallops. Each leaflet develops functionally significant regional variations in surface texture and its core condenses as a collagenous fibrous lamina, supported either by the fibro-fatty tissue of the atrioventricular groove, or by a fibrous anulus. The anterior leaflet of the tricuspid valve and the aortic and mural leaflets of the mitral valve all appear at about the time of fusion of the atrioventricular and outflow cushions. Delamination of the septal leaflet of the tricuspid valve occurs after the completion of ventricular septation, producing the interventricular and atrioventricular components of the membranous septum, and continuing until at least week 11 (Fig. 59.16B).
Aortic and pulmonary valves

The aortic and pulmonary valves form from endocardial cushions within the distal end of the myocardial outflow tract and become populated by neural crest cells, in addition to endocardial and pharyngeal derived mesenchyme. The fusing outflow cushions divide, providing two rudiments each for the developing aortic and pulmonary valves. The remaining leaflet for each valve is then produced from the newly appearing intercalated cushions (Fig. 59.15). Each cushion-derived intrusion grows, and is also excavated on its mural aspect to form a semilunar valvular leaflet. Similar events affect the adjacent wall. In this way, the pouches between the valves and the walls of the cushions gradually enlarge, the mural aspect of each cushion forming the valvular sinuses. The core of each leaflet forms a collagenous fibrous lamina, delicate and thin in each crescentic lunule, thick and compact in the central nodule, with marginal radiate and basal bands. The dynamic nature of cardiac development makes it difficult to describe the positions of the leaflets precisely in space and therefore it is best to describe the right, left, and non-coronary sinuses and leaflets of the aortic valve, and the adjacent and non-adjacent leaflets of the pulmonary valve.
FETAL CIRCULATION

As the cardiovascular system develops, the embryonic circulation (see Ch. 13) is modified into a fetal circulation which maintains a placental circulation and is also able to establish the pulmonary circulation at birth. Extensive remodeling of the early aortic arch arteries and (initially bilateral) dorsal aortae occurs (see Ch. 35). The dorsal aortae persist on the cranial side of the third aortic arches as continuations of the internal carotid arteries (see Fig. 35.8). The dorsal aorta between the third and fourth aortic arches, the carotid duct, diminishes and finally disappears. From the fourth arch to the origin of the seventh intersegmental artery, the right dorsal aorta becomes part of the right subclavian artery, and caudal to the seventh intersegmental artery, the right dorsal aorta disappears as far as the locus of fusion of the thoracic aortae. After disappearance of the left carotid duct, the remainder persists to form the descending part of the arch of the aorta. The fused right and left embryonic dorsal aortae persist as the definitive descending thoracic and abdominal aorta. A constriction, the aortic isthmus, is sometimes present in the aorta between the final site of origin of the left subclavian artery and the orifice of the arterial duct.

Concomitant changes also occur in the early venous system. The precardinal veins enlarge as the head and brain develop. They are further augmented by the subclavian veins from the upper limb buds, which become the chief tributaries of the common cardinal veins, gradually assuming an almost vertical position as the heart descends into the thorax (see Fig. 13.4). That part of the original precardinal vein rostral to the subclavian vein is now the internal jugular vein, and their confluence is the brachiocephalic vein of each side. The right and left common cardinal veins are originally of the same diameter: by the development of a large oblique transverse connection, the left brachiocephalic vein carries blood across from the left to the right (see Fig. 13.4). The part of the original right precardinal vein between the junction of the two brachiocephalic veins and the azygos veins forms the upper part of the superior vena cava. The caudal part of this vessel, below the entrance of the azygos vein, is formed by the right common cardinal vein. The left precardinal and left common cardinal veins caudal to the transverse branching of the left brachiocephalic vein largely atrophy: the precardinal constitutes the terminal part of the left superior intercostal vein, while the common cardinal is represented by the ligament of the left superior vena cava and the oblique vein of the left atrium (see Fig. 13.4). The remainder of the left superior intercostal vein is developed from the cranial end of the postcardinal vein and drains the second, third and, on occasion, the fourth, intercostal veins. The oblique vein passes downwards across the back of the left atrium to open into the coronary sinus, which represents the persistent left horn of the systemic venous sinus.
The fetal circulation contains a number of relatively large vessels which permit the majority of the blood flow to bypass the liver and lungs. The placenta serves as the organ for fetal nutrition and excretion, receiving deoxygenated fetal blood and returning it oxygenated and detoxified. Fetal blood reaches the placenta via two umbilical arteries and in early fetal life returns by two umbilical veins (Fig. 59.17). The right umbilical vein later disappears, whereas the persisting left umbilical vein enters the abdomen at the umbilicus, traverses the edge of the falciform ligament to reach the hepatic surface, and then joins the left branch of the portal vein at the hepatic portal. Opposite the junction, a large vessel, the ductus venosus, arises and ascends posterior to the liver to join the left hepatic vein near its termination in the inferior vena cava. (For a detailed developmental account of the circumhepatic veins, see Ch. 73, Figs 73.8–73.10.) The portal vein is small in the fetus compared to the size of the umbilical vein. Parts of the left branch of the umbilical vein, proximal and distal to their junctions, function as branches of the portal vein, carrying oxygenated blood to the right and left parts of the liver. Blood in the left umbilical vein therefore reaches the inferior vena cava by three routes: some enters the liver directly and reaches the vena cava via the hepatic veins; a considerable quantity circulates through the liver with portal venous blood before also entering by the hepatic veins; the remainder is bypassed into the inferior vena cava by the ductus venosus.
The refreshed placental blood passes almost directly to the aorta for distribution to the head and upper limbs. Blood from the ductus venosus and hepatic veins mixes in the inferior vena cava with blood from the lower limbs and abdominal wall and enters the right atrium. Because right atrial pressure is much greater than left atrial pressure, it forces the flap-like valve of the septum primum to the left, which permits passage of blood from the right to
the left atrium. The valve of the inferior vena cava is so placed as to direct 75% of the richly oxygenated blood from the umbilical vein to the foramen ovale and left atrium, where it mingles with the limited venous return from the pulmonary veins. From the left atrium, blood enters the left ventricle and thence the aorta, by which it is probably distributed almost entirely to the heart, head and upper limbs, which means that little reaches the descending aorta.

Blood from the head and upper limbs returns to the right atrium via the superior vena cava, flows through the right atrioventricular orifice into the right ventricle (together with the small amount of blood that is returned via the inferior vena cava), and then passes into the pulmonary trunk. However, because the fetal lungs are largely inactive, only a little of the blood from the right ventricle flows through the right and left pulmonary arteries and returns to the left atrium via the pulmonary veins. The greater part of the outflow through the pulmonary trunk is carried by the ductus arteriosus directly to the aorta, where it mixes with the small quantity of blood that passes from the left ventricle into this part of the aorta. The mixture descends in the aorta and most is returned via the umbilical arteries to the placenta: some is distributed to the lower limbs and the organs of the abdomen and pelvis.
CHANGES IN THE FETAL CIRCULATION AND OCCLUSION OF FETAL VESSELS AFTER BIRTH

At birth, as pulmonary respiration begins, increased amounts of blood from the pulmonary trunk flow through the pulmonary arteries to the lungs and return by the pulmonary veins to the left atrium: pressure therefore increases within the left atrium. A decrease in pressure also occurs in the inferior vena cava as a result of the reduction of venous return concomitant with occlusion of the umbilical vein and ductus venosus. Atrial pressures become equal and the valvular foramen ovale is closed by apposition, and subsequent fusion, of the septum primum to the rims of the foramen. Contraction of the atrial septal muscle, synchronized with that in the superior vena cava, may assist this closure, which occurs after functional closure of the ductus arteriosus. Although the foramen ovale closes functionally after pulmonary respiration is established, it does not become structurally closed until some time later. It is obliterated in fewer than 3% of infants 2 weeks after birth, and in 87% by 4 months after birth. Fusion is sometimes incomplete and a potential atrial communication (atrial septal defect) persists throughout life. Almost always this has no functional effect, because the inequality of atrial pressures and the valve-like arrangement of the opening do not favour passage of blood.

Soon after birth, a number of fetal vessels occlude, although the majority remain patent. This differential constriction suggests that the walls of a population of fetal vessels are different to those of the remaining vessels. Bradykinin, one of the kinin polypeptide hormones which induce contraction or relaxation of smooth muscle, forms in the blood of the umbilical cord when the temperature of the cord decreases at or shortly after birth. It is also formed and released by granular leukocytes in the lungs of the neonate after exposure to adequate oxygen. Bradykinin is a potent constrictor of the umbilical arteries and veins and of the ductus arteriosus, and is also a potent inhibitor of contraction of the pulmonary vessels.

Ductus arteriosus

The ductus arteriosus shunts blood from the pulmonary trunk to the arch of the aorta, bypassing the fetal lungs (Figs 59.17, 59.18). It arises as a direct continuation of the pulmonary trunk at the point where it divides into right and left pulmonary arteries. It is 8–12 mm long, and joins the aorta at an angle of 30–35° on the left side, anterolaterally, below the origin of the left subclavian artery. The opening of the ductus arteriosus into the aorta is greatly elongated. Its diameter at its origin from the pulmonary trunk, when distended with blood, is 4–5 mm, which is nearly equal to the diameter of the adjacent ascending aorta (5–6 mm). Both arteries taper to a smaller diameter as they pass inferiorly and the aorta remains slightly larger (4 mm) (Fig. 59.19). In the neonate, the ductus arteriosus is closely related to the left primary bronchus inferiorly and the thymus gland anteriorly.
Fig. 59.18  Anterior view of heart and great vessels in a full-term neonate. The lungs have been displaced to expose the heart and the epicardium dissected off the heart and roots of the great vessels. Note that, after birth, blood flow reverses through the ductus arteriosus prior to its closure. (After Crelin ES 1969 Anatomy of the Newborn. Philadelphia: Lea and Febiger.)
The ductus arteriosus differs from the other great vessels which arise from the heart because its tunica media contains smooth muscle rather than layers of elastin. It has been suggested that the relationship between the recurrent laryngeal branch of the vagus nerve and the developing ductus arteriosus is responsible for this histological difference on the grounds that the left recurrent laryngeal nerve (which, in a stage 16 embryo, is very large in relation to the aortic arch system) supports the ductus arteriosus as it enwraps it, thereby...
permitting the ductus to develop as a muscular, and not an elastic, artery.

It is essential that the ductus arteriosus remains patent during intrauterine life. Prostaglandins appear to have a role in maintaining this patency. Fetal and neonatal ductal tissue can produce prostaglandins E$_2$, I$_2$ and F$_2$α, which inhibit the ability of the ductus to contract in response to oxygen.

**Closure of the ductus arteriosus**

The ductus arteriosus starts to close immediately after birth, although blood probably continues to flow intermittently through it for a week or so. The flow is reversed relative to that occurring in the fetal circulation, reflecting the increased systemic vascular resistance which follows exclusion of the placental circulation, and the decreased pulmonary resistance which follows expansion of the lungs. Initial constriction at birth has been attributed to increased oxygen tension. A neural factor may also be involved: the muscular wall has afferent and efferent nerve endings and responds to adrenaline and noradrenaline.

The first stage of ductal closure is completed within 10–15 hours and the second stage takes 2–3 weeks. The first stage consists of contraction of the smooth muscle cells and development of subendothelial oedema. Destruction of the endothelium and proliferation of the intima subsequently occurs, and leads to permanent closure. Diverse factors which may promote ductal closure have been identified. They include: increased oxygen tension; increased plasma catecholamine concentrations; suppression of prostaglandin I$_2$ production; switching off prostaglandin E receptors; a synergistic role of prostaglandin F$_2$α and oxygen concentrations; a decrease in plasma adenosine concentration. After birth, these interrelated events result in the closure of the ductus arteriosus. It has been proposed that the high oxygen tension of the reversed blood flow through the ductus initiates the synthesis of a hydroperoxy fatty acid which suppresses prostacyclin production, thus exposing the ductus to the contractile effects of prostaglandin endoperoxide. After closure, the duct becomes the ligamentum arteriosum, which connects the left pulmonary artery (near its origin) with the aortic arch.
FETAL AND NEONATAL HEART

At full term, the heart is situated midway between the crown of the head and the lower level of the buttocks (see Fig. 14.4). The anterior surface is formed mainly by the right atrium and right ventricle, as it is in the adult. This surface is usually covered by the thymus, which may extend over the base of the right ventricle. The heart is relatively large at birth, weighing around 20 grams. The cardiac output is around 550 ml per minute, and the blood pressure is 80/46 mmHg. The heart rate during fetal life, as term approaches, is around 150 beats per minute. It increases at birth to around 180 beats, decreases over the first 10 minutes after birth to 170 beats, and reaches 120–140 beats per minute from 15 minutes to 1 hour after birth. Any signs of fetal distress will increase this general basic level. The heart rate decreases further with increasing age: it is normally 113–127 beats per minute from 6 months to 1 year, and settles to around 100 beats per minute by the end of the first year.

Considered relative to the thoracic landmarks, the foramen ovale lies at the level of the third intercostal space, with its long axis in the median plane. It is 4–6 mm in vertical length and 3–4 mm wide (see Fig. 14.4). It is almost exactly in the coronal plane of the body, so that blood passes from the anterior, or ventral, right atrium posteriorly and upwards to reach the upper and posterior part of the left atrium. After birth, the intra-atrial pressures are equalized, and the free edge of the flap valve formed by the primary atrial septum is kept in contact with the left side of the rims of the fossa, promoting subsequent anatomic fusion, albeit that the foramen remains probe-patent in up to one-third of all individuals. The initially free crescentic margin of the infolded superior interatrial fold forms the border of the fossa after fusion; the flap valve formed by the primary septum accounts for its floor in the adult heart.

Functionally, the ventricular septum is often considered to be part of the left ventricle: while this is certainly true in terms of the orientation of the myocardial aggregates which make up the ventricular walls, it is not correct from a cellular lineage perspective. The ratio of cardiac weight is usually expressed as the weight of the right ventricle relative to that of the left ventricle and the septum. Calculated in this fashion, the left ventricle at birth weighs about 25% more than the right ventricle. However, the right ventricle has been working against the systemic pressure in the fetus, the pulmonary circulation not yet being active, and there is a preponderance of right ventricular function in the first 2 or 3 months after birth. With the establishment of the pulmonary circulation, the work of the right side of the heart decreases, and the left side of the heart, particularly the ventricle, grows rapidly to meet the demands of the active neonate. By the end of the second year, the left side weighs twice as much as the right, a ratio that
continues to middle age. At birth, the average thicknesses of the lateral walls of the ventricles are approximately equal (5 mm). By the end of the third postnatal month, the left ventricle has already become thicker than the right, it becomes twice as thick by the second year, and three times as thick by puberty.
CONGENITAL HEART DEFECTS

Defects of cardiac development may not come to light until after birth, although many, if not most, can now be observed on fetal ultrasonic examination. They may affect any part of the developing heart, and include more complex forms with inappropriate connections of cardiac components. They include anomalies such as double inlet ventricle; absence of one atrioventricular connection, commonly described as tricuspid or mitral atresia; and discordant atrioventricular and ventriculo-arterial connections, also known as congenitally corrected transposition.

Congenital cardiac malformations are often multiple, and probably occur more frequently in siblings and in children of consanguineous marriages: there is a low correlation among monozygotic twins. Ventricular septal defects are the most common lesions, making up around one-fifth of all cases, followed by persistent patency of the ductus arteriosus, coarctation, pulmonary stenosis, Fallot’s tetralogy, transposition, aortic stenosis, and hypoplasia of the left heart.

**Atrial septal defects**

A persistent communication between the atrial chambers within the fossa ovale is common, and results from the failure of the flap valve of the primary atrial septum to fuse with the infolded muscular rims of the fossa. When the flap valve is still able to overlap the rims, the communication is of no functional significance as long as left atrial pressure is greater than right, which is usually the case. However, when the flap valve is smaller than the fossa ovale, or when it is perforate, there is a true atrial septal defect (Fig. 59.20A).
In normal development, the free leading edge of the septum primum merges with the atrioventricular endocardial cushions, permitting subsequent formation of the atrioventricular septum. When this does not happen, there is a common atrioventricular junction and an atrioventricular septal defect. This can occur when the leaflets of the atrioventricular valves are fused to the crest of the ventricular septum (Fig. 59.20A), producing an interatrial communication at the expected site of the atrioventricular septum. This is the so-called ostium primum defect, and in reality is an atrioventricular septal defect permitting exclusive atrial shunting. Other interatrial communications can be formed in the mouths of the vena cavae, most frequently the superior vena cava, and are usually associated with drainage of the right pulmonary veins into the cavo-atrial junction. Known as sinus venosus defects (Fig. 59.20A), their essential feature is a bi-atrial connection of the involved caval vein. An interatrial communication can also occur through the mouth of the coronary sinus when there is a deficiency or absence of the walls that usually separate the sinus from the left atrium.

Atrioventricular septal defects result from failure of fusion of the endocardial atrioventricular cushions, producing a common atrioventricular orifice and deficiencies of the adjacent septal structures (Fig. 59.20B). The common orifice is guarded by a basically common valve, with superior and inferior leaflets bridging the scooped-out ventricular septum and tethered in both right and left ventricles. Although the left component of the valve thus formed is often interpreted as a ‘cleft mitral valve’, in reality it bears no resemblance to the normally structured mitral valve, because it has three leaflets; the ‘cleft’ forms the zone of apposition between the left ventricular components of the bridging leaflets. Two major subgroups are identified. The more frequent pattern has a common atrioventricular orifice, and the potential for shunting through the septal defect at both atrial and ventricular levels (Fig. 59.20B). The less common form has separate right and left atrioventricular orifices, and shunting occurs only at atrial level. Occasionally, when the bridging leaflets are attached to the
underside of the atrial septum, shunting is confined at ventricular level, and is typically small.

**Ventricular septal defects**

The most common defect of the ventricular septum occurs around the expected site of the membranous septum in the right wall of the aortic vestibule, below the zone of apposition between the non-coronary and right coronary leaflets of the aortic valve (Fig. 59.20C). The defect is closely related to the septal leaflet of the tricuspid valve, but can extend to open into the ventricular outlet beneath the supraventricular crest. It occurs because the ventricular septum is incompletely closed by its membranous component, and it is often associated with overriding of the crest of the muscular septum by the aortic orifice, together with pulmonary stenosis or atresia and hypertrophy of the right ventricle (this latter combination is known as Fallot's tetralogy). Rarely, the pulmonary trunk can be normal or even dilated with this combination of abnormalities (Eisenmenger complex). Peri-membranous defects, which retain the remnant of the membranous septum as part of their perimeter, can also occur with normal ventriculo-arterial connections, e.g. the pulmonary trunk may override the muscular septum, (the Taussig–Bing anomaly). In perimembranous ventricular septal defects, the atroventricular bundle and its right and left branches are always found along the postero-inferior margin of the defect.

Less commonly, a septal defect can be found in the ventricular outflow tracts roofed by the conjoined facing leaflets of the aortic and pulmonary valves. Such juxta-arterial defects are doubly committed, in that they open beneath the orifices of both aortic and pulmonary valves. They are the result of the failure of formation of the free-standing subpulmonary muscular infundibulum, but with appropriate septation of the ventriculo-arterial junctions. They usually have a muscular postero-inferior rim, which protects the atroventricular bundle, but can extend to become peri-membranous.

The third type of ventricular septal defect occurs within the musculature of the septum: defects may affect all parts of the septum, and can be multiple, producing a so-called ‘Swiss-cheese’ septum.

Defects within the inlet part of the septum are important, because the atroventricular bundle passes in their upper border. Perimembranous defects open into the inlet of the right ventricle, where the atroventricular bundle is postero-inferiorly located.
ABNORMAL CONNECTIONS OF THE GREAT ARTERIES AND VEINS

A number of outflow anomalies may occur should the outflow cushions either fail to develop, or fuse in inappropriate fashion. When the spiral septum cushions fail to fuse, the result is a common arterial trunk, represented by an undivided arterial channel, guarded by a common arterial valve, positioned above and astride the free margin of the muscular ventricular septum (Fig. 59.21). There is, therefore, a coexisting juxta-arterial deficiency of the ventricular septum. The right and left pulmonary arteries usually arise via a confluent segment, but can take independent origin from the common arterial trunk, which continues as the ascending aorta. The common valve usually has three leaflets, but may have two, four or more. The lesion is almost certainly linked to abnormal migration of cells into the heart from the neural crest.
Transposition of the arterial trunks (also referred to as transposition of the great vessels) is the condition in which the aorta arises from the right ventricle and the pulmonary trunk from the left. Better described as having
discordant ventriculo-arterial connections, such hearts can co-exist with deficiencies of cardiac septation. They can also be found with discordant connections at the atroventricular junctions, producing congenitally corrected transposition. The developmental history of discordant connections remains unknown.

Double outlet ventricle exists when the greater parts of both arterial valves are attached within the same ventricle, almost always the right. For the circulation to continue, it is then necessary for the ventricular septum to be deficient, although the septal defect can rarely close as a secondary event. The position of the septal defect serves for subclassification. It is usually beneath the aorta or the pulmonary trunk, but can be doubly committed or even non-committed.

Either the systemic or pulmonary veins can be anomalously connected. Right and left superior vena cavae are present in some animals, and occasionally persist in mankind. The most common systemic anomaly is a persistent left superior vena cava draining into the right atrium through the enlarged orifice of the coronary sinus. More rarely, the persisting left-sided vena cava may connect directly with the superior aspect of the left atrium, usually associated with so-called ‘unroofing’ of the coronary sinus, so that the orifice of the sinus functions as an interatrial communication. The most common lesion of the inferior vena cava is when its abdominal course is interrupted, with drainage to the heart via the azygos or hemiazygos venous system. This lesion is found most frequently with isomerism of the left atrial appendages. The pulmonary veins can be connected to an anomalous site individually or in combination. Totally anomalous connection is of most significance. Usually, the veins form a confluence behind the left atrium that then connects to the superior vena cava, the coronary sinus, or the portal venous system after traversing the diaphragm.

A right aortic arch is found most frequently with Fallot’s tetralogy or with a common arterial trunk. It can also exist, together with a left arch, in various combinations known as arterial rings, which compress the oesophagus, giving so-called dysphagia lusoria. Persistent patency of the ductus arteriosus must be distinguished from delayed closure. The persistently patent ductus can be an obligatory part of the circulation when associated with aortic or pulmonary atresia. Coarctation of the aorta can be found as an isolated lesion when the ductus arteriosus is closed, or with an open duct, when it is more likely to be associated with additional lesions within the heart (see p. 984).

In the adult, the right subclavian artery occasionally arises from the arch of the aorta distal to the origin of the left subclavian artery, and then passes upwards and to the right, behind the trachea and oesophagus. This condition is possibly explained by the persistence of the embryonic right dorsal aorta
and the obliteration of the fourth aortic arch of the right side.
NEONATAL ARTERIAL AND VENOUS VESSELS

In the neonate, the blood vessels of the trunk and their associated visceral branches are relatively larger than the vessels in the limbs, an arrangement which favours central pooling of blood. Neonatal peripheral vessels are nearly microscopic: their cannulation consequently poses much more of a problem than is the case with their adult counterparts. Large vessels are in the same relative positions as in the adult, but may correspond to different vertebral levels. Thus, although the bifurcation of the common carotid artery into internal and external carotid arteries occurs at the level of the upper border of the thyroid cartilage, in both neonate and adult, the thyroid cartilage is relatively higher in the neonatal neck than it is in the adult. The renal arteries also arise higher in the neonate, often between T12 and L1, whereas they arise at the upper border of L2 in the adult. The abdominal aorta bifurcates into common iliac arteries at the upper border of L4, rather than at the lower border of L4 as occurs in the adult.

Central venous catheterization

Small-bore catheters can be fed into large central veins or into the right atrium via needles or catheters inserted in the peripheral veins. Typically, the median cubital or basilic veins are used in the upper limb and the long saphenous vein at the medial malleolus in the lower limb. The tip of the catheter is sited at the entrance to the right atrium. The required catheter length is assessed from direct measurement of the distance between the point of surface entry in the limb to the right atrium, estimated at midsternal level. For details of umbilical catheterization, see Chapter 73.
RESPIRATORY TREE

The development of the respiratory system can be conceptualized as the growth of six intertwined trees: the bronchial tree of conducting airways and exchange spaces; the systemic arterial and venous trees supplying the airways; the pulmonary arterial and venous trees which will provide blood oxygenation after birth; the lymphatic tree. Development of each tree is related to the other and all proceed in proximal to distal growth and expansion.

The development of the respiratory diverticulum can first be seen at stage 12 (approximately 26 days), when there is a sharp onset of epithelial proliferation within the foregut at regions of the endoderm tube destined to become the lungs, stomach, liver and dorsal pancreas. The specialist respiratory epithelium forms from the endoderm; the other elements of the airway wall are of mesenchymal origin. The future respiratory epithelium bulges ventrally into the investing splanchnopleuric mesenchyme, then grows caudally as a bulb-shaped tube (Figs 59.1, 59.22; see Fig. 73.9). By stage 13, the caudal end of the tube has divided asymmetrically to form the future primary bronchi: with growth the right primary bronchus becomes orientated more caudally whereas the left extends more transversely. The trachea is clearly recognizable at stage 14. From this time the origin of the trachea remains close to its site of evagination from the future oesophagus, however, longitudinal growth of the trachea causes the region of the future carina to descend. Failure of complete separation between trachea and oesophagus will result in the baby being born with a tracheo-oesophageal fistula (see below). Lung development is controlled by groups of homeobox genes, transcription factors and growth factors (summarized in detail by Roth-Kleiner & Post 2005). The formation of the lung bud is dependent on the transcription factors hepatocyte nuclear factor-3β (HNF-3β), thyroid transcription factor (TTF-1) and sonic hedgehog (SHH). Gli proteins and retinoic acid receptors are implicated in the mesenchymal-epithelial cell interactions that are essential for lung branching morphogenesis.
There is a sexual dimorphism in lung development. Androgens delay fetal lung maturation while stimulating fetal lung growth: in males, type II cells are less mature than in females as they develop during the cannalicular phase, perhaps because androgens block the effects of cortisol on fibroblast–pneumocyte factor concentrations. It is possible that in male fetuses surfactant production is delayed. The clinical counterpart is the observation...
that preterm males may have worse respiratory distress than females after control for other risk factors such as degree of prematurity.

**TRACHEA**

The trachea starts to develop at stage 12, as a ventral outgrowth from the endodermal foregut into the mesenchyme surrounding the sinus venosus and inflow tract of the heart (Fig. 59.1B,C; see Figs 73.3, 73.5). The point at which the original respiratory diverticulum buds from the foregut, the laryngotracheal groove, remains at a constant level during the embryonic period, and the trachea lengthens distally as the bifurcation point descends. The respiratory diverticulum generally becomes surrounded by angiogenic mesenchyme which connects to the developing sixth aortic arch artery and which is essential for airway branching. By stage 17, the mesenchyme around the trachea is beginning to condense to form cartilage.

Initially, the tracheal mesenchyme is continuous with that surrounding the ventral wall of the oesophagus (Fig. 59.3). Progressive lengthening and continued division of the tracheal bud, together with deviation of the lung buds dorsally, isolates the oesophagus and trachea within tissue-specific mesenchyme and facilitates regional differentiation, not only between trachea and lungs, but also within the lungs themselves, i.e. the number of lobes, or the degree of growth and maturity of a particular lung. Each lung develops by a process of dichotomous branching. For branching to occur, a cleft must develop in the tip (or side) of the epithelial tube. The epithelium then evaginates each side of the cleft, forming new branches which lengthen, and the process is then repeated. At the tips of the developing epithelial buds, the mesenchyme is flattened and densely packed, whereas it forms an ordered row of cuboidal cells along the side of the bud and in the clefts. Cells in both arrangements send processes towards the epithelial basal lamina, which is thicker in the clefts, but so attenuated as to be almost indistinguishable on the tips of the buds where the epithelium and mesenchymal cells form intimate contacts. Tenascin, an extracellular matrix molecule, is present in the budding and distal tip regions, but absent in the clefts. Conversely, fibronectin, an extracellular matrix molecule found commonly in basal laminae, is found in the clefts and along the sides of the developing bronchi, but not on the budding and distal tips.

The control of the branching pattern of the respiratory tree resides with the splanchnopleuric mesenchyme. Experimental recombination of tracheal mesenchyme with bronchial respiratory endoderm results in inhibition of bronchial branching, whereas recombination of bronchial mesenchyme with tracheal epithelium will induce bronchial outgrowths from the trachea. Experimental exposure of rat fetal airway to chick mesenchyme produces a chick airway branching pattern. Broadly, receptor tyrosine kinases and their ligands positively modulate growth and branching morphogenesis, while
transforming growth factor β (TGF β) family members have an inhibitory effect.

In the normal neonate, the trachea is relatively small in relation to the larynx (Fig. 14.4). The walls of the trachea are relatively thick and the tracheal cartilages are relatively closer together than in the adult. The trachea begins at the upper border of the sixth cervical vertebra, a relationship that is conserved with growth, and it bifurcates at the level of the third or fourth thoracic vertebra.

**Endotracheal intubation in the neonate**

The insertion of an endotracheal tube is a procedure that may be required for resuscitation of the newborn at birth and subsequently to enable artificial ventilation. The tube is introduced usually orally initially and guided through the vocal cords with the help of a laryngoscope. The length of the trachea in the neonate can be as short as 3.1 cm in premature infants, and the T1-to-carina distance ranges from 1.4 cm in babies weighing 500–1000 g, to 1.8 cm in those weighing 3001–3500 g. Once in place, the tip of the tube should be in the midtrachea, well above the carina.

The required length of the tube can be estimated according to birth weight. If a shouldered tube is used, only the distal, tapered portion of the tube is inserted beyond the vocal cords, and the shoulders should prevent the tube being advanced too far. Confirmation of correct positioning of the endotracheal tube is obtained from a chest X-ray. The anatomical reference points used for the X-ray to assess the position of the endotracheal tube are the clavicles, the bodies of the vertebrae and the carina (although the last of these is not always visible on X-ray). Previously, it was advised that the tip of the endotracheal tube should be placed just below the clavicles, at the level of the first rib or 1–2 cm above the carina. Recently, this has been revised because positioning of the clavicles can vary according to angulation and placement of the baby, and the carina cannot always be identified. It is now suggested that the body of the first thoracic vertebra (T1) is a more stable reference point as the target for the tip of the endotracheal tube.
LUNGS

Branching of the conducting airways is generally complete by week 16. Airways subsequently increase in size, but not in number. Alveolar development is largely (but not completely) a postnatal phenomenon. The development of pre-acinar blood vessels follows the conducting airway development, whereas development of intra-acinar blood vessels follows the development of the alveolar ducts and alveolar sacs. Lung development is described histologically as progressing through embryonic, pseudoglandular, canalicular, saccular and alveolar phases. (For further details see Rosenthal & Bush 2002; Bush 2005.)

Embryonic phase

The lung buds grow dorsally, passing each side of the relatively smaller oesophagus and bulge into the medial walls of the laterally situated pericardioperitoneal canals (Fig. 59.22; see Fig. 73.5A). The investing splanchnopleuric mesenchyme surrounding the lung buds contains a mixed population of cells. Further mesenchymal cells will differentiate into the smooth muscle cells that surround both the respiratory tubes and the blood vessels. In stage 13 embryos, proliferation of the adjacent splanchnopleuric coelomic epithelium (of the primary pleural cavities) is especially evident. The proliferative activity decreases in stage 14, and the mesenchyme becomes arranged in zones around the developing endoderm. Key molecules in airway branching include the fibroblast growth factors (FGF) especially FGF-10, and their four receptors. There is almost certainly redundancy in the system, since mice null for either FGF-1 or FGF-7 exhibit normal lung development, despite the potent in vitro effects of these mediators. The key receptor appears to be FGFR2IIIb, and those ligands that bind it. SHH is another gene important in lung development: it is tightly regulated and over-expression leads to the formation of excessive lung mesenchyme. The three members of the gli family of transcription factors are implicated in SHH signalling. SHH produced in distal epithelial cells appears to act on mesenchymal cells to suppress FGF-10 to limit budding. Other signals interacting with this process include bone morphogenetic protein 4 and TGF-β1.

At stage 15, angiogenetic mesenchyme is apparent around the primary bronchi. It forms an extensive capillary network around each lung bud, receiving blood from the developing sixth aortic arch artery and draining it into an anastomosis connected to the dorsal surface of the left atrium in the mediastinal mesenchyme. The pulmonary arteries arise from the sixth aortic arch arteries and the pulmonary veins develop from a solitary channel derived from the dorsal mesocardium which establishes continuity with the vascular plexus formed in the mediastinal mesenchyme. The pulmonary veins become surrounded by myocardium to the level of the second bifurcation; the veins themselves expand and are incorporated into the roof of
the left atrium: cardiac muscle is therefore found in the central branches of the pulmonary venous tree (Hislop 2005).

The lung buds on each side of the oesophagus project dorsally into the pericardioperitoneal canals at stage 15. After this stage, the coelomic epithelium at the perimeter of the lung surface follows a differentiation pathway to form the visceral pleura. Lobar or secondary bronchi can be seen at stage 16, and the bronchopulmonary segments are present at stage 17 (see Fig. 73.3). Later stages of respiratory development involve the repeated division of the bronchial tree to form the subsegmental bronchi.

**Pseudoglandular phase**

By stage 17 (late sixth to early seventh week), the separation of the lungs from the digestive system is complete and the pseudoglandular phase of pulmonary development, which includes the development of the lower conducting airways and the appearance of the acinar structures, can be identified. During this period, virtually the complete branching structure of the future bronchial tree is laid down, giving rise to 20 generations.

The growth and branching of the endoderm epithelium is controlled by the local investing splanchnopleuric mesenchyme. The airways begin to differentiate during this stage. Primitive ciliated cells appear at about week 7, initially in the region of the membranous trachea, and in the cartilaginous region by week 12. The *in utero* function of these early ciliated cells in the trachea is obscure; elsewhere in the embryo, primary cilia have important developmental functions, e.g. in determining organ situs (nodal cilia). It is unclear whether airway ciliated cells develop from an undifferentiated precursor, or through the further development of a population of secretory cells. The epithelium differentiates into ciliated and goblet cells. The proximal airways develop basal cells from week 11, and ciliogenesis is complete at birth in humans. Mucous glands develop by 12 weeks and enlarge in the submucosa: secretory activity has been identified in the trachea at 14 weeks. The splanchnopleuric mesenchyme condenses around the epithelium and differentiates into connective tissue cell types and smooth muscle, which differentiates proximal to the tips of the developing airways as they develop, from week 6 onwards. Smooth muscle cells are innervated from as early as week 8 (see below). First trimester human tracheal smooth muscle cells have a fluctuating resting membrane potential which is associated with the spontaneous development of tone and peristalsis-like contractions of the airway of a myogenic nature, probably modified by neuro-humoral factors. These contractions are important in moving fluid from distal to proximal within the airways, which is essential for normal lung development, and may stimulate mediator release. Clara cells develop in the peripheral airways during the pseudoglandular period. They produce a 10-kDa protein (CC10) which has immuno-modulatory and anti-inflammatory activity as well as
producing a surfactant apoprotein. Cartilage also develops during this period, and is found in the airways in an adult distribution by 24 weeks. By the end of this period, the airway branching and the pre-acinar vascular patterns are fully mature. A normal airway ‘template’ is essential for normal alveolar formation: in conditions characterized by an abnormal airway branching pattern (e.g. both ipsilateral and contralateral to a diaphragmatic hernia), a degree of pulmonary alveolar hypoplasia is inevitable.

Endothelial development is also seen in the pseudoglandular phase when capillary networks form around the developing lung buds. These networks will become capillary anastomoses around the future alveoli. The mesenchyme produces both the endothelium and the smooth muscle cells of the tunica media of the vessels. Vimentin occurs in the cells around developing vessels in the pseudoglandular stage, but is replaced by desmin in the saccular phase.

**Canalicular phase**

During the canalicular phase, about two to three generations of branching take place, after which the amount of mesenchyme around the branching tips of the dividing respiratory tree decreases and the distal airspaces widen. At 23 weeks, longitudinal sections of the future distal regions show a sawtooth margin, which may indicate the site of further acini. Peripheral growth is accompanied by an increase in the capillary network around the distal airspaces. In many places, the capillaries are in close contact with the respiratory cuboidal epithelium. The primitive cuboidal cells, which hitherto predominated in this part of the lung, differentiate into Type 2 epithelial cells (pneumocytes), containing lamellar bodies which form the intracellular storage bodies of surfactant, and Type 1 epithelial cells (pneumocytes). Type II pneumocytes are believed to be the stem cells of the alveolar epithelium. Apposition of the capillary networks to the thin pneumocytes (Type 1), and reduction of the interstitial tissue of the lung, are prerequisites for future effective gas exchange. By 24 weeks of gestation the histological characteristics of the airways are the same as in the adult.

**Saccular phase**

Thin walled terminal saccules are apparent at the saccular stage: they will become alveolar ducts as development proceeds. The expansion of the prospective respiratory airspaces which occurs during this period is accompanied by a further decrease in the amount of interstitial tissue, and the capillary networks become ever more closely opposed to the pneumocyte epithelium. Invaginations termed secondary crests develop from the saccule walls. As a crest protrudes into a saccule, part of the capillary network becomes drawn into it. After the later expansion of the saccules on each side of the crest, a double capillary layer becomes annexed between what are
now alveolar walls. During the saccular stage, elastin is deposited beneath the epithelium (an important step for future alveolar formation), and surfactant production, from Type 2 pneumocytes, matures (essential for the survival of a preterm neonate).

**Alveolar phase**

Exactly when the saccular structure of the lung can be termed alveolar is not yet clear: opinions range from 28 to 32 weeks. The distal airspaces expand during late gestation and continue to do so after birth. This process is accompanied by fusion of adjacent capillary nets, so that shortly after birth there is an extensive double capillary net. Fusion of these layers is apparent at 28 days postnatally and extensive at 1.5 years; it is probably complete by 5 years. The alveolar stage continues into childhood, perhaps up to 8 years of age, although the balance of the evidence is that most alveoli are present by two years of age. The number of alveoli present at birth (variably estimated as between none to \(5 \times 10^7\)) and the age at end of alveolarization (estimated at between 2 and 20 years) is controversial. The process of forming new alveoli is rapid for six months, and by then mostly complete, with a plateau phase to two years with formation of alveoli largely complete at this time. Thereafter, probably growth of new alveoli is minimal.

The formation of millions of alveoli is accomplished by a complex process of folding and division. Existing walls of distal airspaces become thinner as pneumocyte epithelial cells flatten, and some cells undergo apoptosis. Ridges subsequently grow out from the sides of the saccule walls, forming primitive alveoli. The secondary septa contain a double capillary layer, and further new alveoli form by the infolding of one of these layers, further subdividing the air spaces. The double capillary networks then undergo remodeling to form the familiar single capillary sheet around each alveolus. Conducting airways also undergo profound postnatal changes, and exhibit increased smooth muscle and bronchoconstrictor responsiveness. Although the precise molecular signalling for these processes is unknown, it is acknowledged to be tightly developmentally regulated, thus dexamethasone treatment of rats during the alveolarization period permanently abrogates alveolar development. This finding implies that iatrogenic damage to the developing alveoli when ventilating a preterm baby with oxygen-enriched mixtures is probably irreversible.

It is becoming clear that elastin gene expression, possibly modulated through retinoic acid, is of pivotal importance in alveolar budding. Retinoic acid treatment of rats increases alveolarization, and salvages some alveoli in the steroid treatment model, whereas mice with a deletion in the retinoic acid receptor \(\gamma\) have impaired alveolarization. Retinoic acid regulates the expression of a number of growth signalling molecules, homeobox genes and lung epithelial genes; other gene groups involved in alveolarization probably
include TGF-β, platelet-derived and fibroblast growth factors.

**Development of the intrapulmonary vasculature and lymphatics**

In an adult lung, the pulmonary arteries accompany the airways. The pulmonary veins have a similar number of branches but are separated from the airways by the alveoli: they have a different embryological origin deriving from the mediastinal mesenchyme proximally rather than splanchnopleuric mesenchyme around the bifurcating respiratory tree. The mesenchyme around the single lung bud contains a number of cells staining positively for CD34 and CD31, which are markers for endothelial cells. The earliest pulmonary vessels form in the mesenchyme by vasculogenesis: the capillaries coalesce to form small blood vessels alongside the airways. By 34 days of gestation, blood circulates from the aortic sac via pulmonary arteries into a capillary plexus around the two lung buds, and drains to the developing atrium. As each new airway forms in the mesenchyme, a new plexus forms as a halo around it, and coalesces with the vessels already alongside the previous airway. In this way, addition of the newly formed tubules to the existing vessels is sustained: the airways acting as a template for the development of blood vessels. Vessel formation occurs at least until the end of the pseudoglandular stage and is probably controlled by production of VEGF from the epithelial cells of the peripheral lung buds. As the arteries increase in size they acquire a muscular wall. Initially this arterial tunica media is derived from the bronchial smooth muscle of the adjacent airways, but as the vessels enlarge further, cells derived from the splanchnopleuric mesenchyme differentiate around the wall to form layers of smooth muscle cells. The muscular wall is thick relative to the lumen and this in part increases resistance to blood flow, although only 10% of blood flow goes through the pulmonary circulation of the lung during intra-uterine life. At 20 weeks, the structure of the pulmonary vessels is the same as it is in the adult. Vascular innervation follows muscularization; the vasoactive peptides in these nerves are predominantly vasoconstrictor.

As the pulmonary veins enlarge they become separated from the airways by lymphatic vessels which lie within connective tissue. At around week 12, the peripheral veins develop a single layer of smooth muscle cells in their walls. This layer is derived only from the splanchnopleuric mesenchyme and not from bronchial smooth muscle (as occurs in the arteries). The lumen of each vein is relatively large and the wall is relatively thin at all levels. Arteries and veins continue to develop in the canalicular phase, probably by angiogenesis; dividing cells are seen in the peripheral capillaries. The epithelium of the most peripheral conducting airways flattens when the developing capillaries come to lie immediately subjacent to it during this phase. (For a review of the development of the pulmonary circulation see Hislop 2005.)

Lymphatic capillaries and vessels run within bronchovascular bundles.
Lymphatic channels develop from outgrowths of vascular endothelial cells. The molecular trigger for lymphatic sprouting is VEGF-C and D, acting through the VEGF receptor 3 (Janér et al 2006).

As well as developing a pulmonary circulation, the lung also develops a bronchial supply from the systemic circulation. Two or three bronchial arteries grow from the descending aorta from week 8 onwards, entering the lung at the hilum. These arteries extend down the intrapulmonary airways, eventually forming sub-epithelial and adventitial plexuses, which by birth have reached the distal portions of the bronchioli. The bronchial veins from the periphery of the lungs drain into the pulmonary veins. Bronchial arteries also supply the pleura near the hilum, and form vasa vasorum in the adventitia of the large arteries and veins. Post-natally, inflammatory lung conditions such as bronchiectasis cause hypertrophy of the bronchial circulation; these vessels may bleed, giving rise to massive haemoptysis in some cases.

**Intra-uterine maturation of the lungs**

There are more than 30 different cell types within the adult lung which mature during development. Only a few important changes which are relevant to human disease will be highlighted here.

Pulmonary surfactant is produced by Type 2 alveolar epithelial cells, and stored in lamellar bodies. It is crucial for maintaining the functional integrity of alveoli: the main morbidity of extreme prematurity reflects surfactant deficiency causing neonatal respiratory distress (treatment has been transformed by the availability of exogenous surfactant). Fetal breathing movements appear to be important in surfactant synthesis: the functional maturation of the surfactant system can be accelerated therapeutically by the administration of steroids to the mother.

Normal lung development requires sufficient intrathoracic space, normal fetal breathing movements and sufficient amniotic fluid. There is evidence that perturbation of fetal lung blood flow also affects lung growth, even though most of the right ventricular output of the heart is shunted away from the lungs through the ductus arteriosus: pulmonary valve stenosis is associated with pulmonary hypoplasia.

Although many fetal organs are able to grow to normal proportions even if they are in abnormal locations, this is not the case for the lungs. Lung growth becomes impaired by restricted expansion, and distension of the developing lung may provide a major stimulus to growth during normal development. Absence or impairment of fetal breathing movements, and defects affecting diaphragmatic activity, are all associated with pulmonary hypoplasia. It is believed that normal fetal breathing movements increase the lung volume and stimulate growth of the distal airspaces. Fetal breathing movements
involve rhythmic activation of the diaphragm and the muscles of the upper respiratory tract. Even though such movements are necessarily very small compared with those seen after birth, because the fetal airways are filled with lung fluid, there is evidence that these phasic movements are important in the release of growth factors.

During development, the mucous glands of the trachea and bronchi secrete a chloride-rich fluid, which usually passes up the respiratory tract to mix with the amniotic fluid. The relationship between lung fluid and amniotic fluid is far more complex than was previously believed. Pulmonary hypoplasia at birth may be associated with severe congenital urinary obstruction and oligohydramnios (Potter's syndrome). In renal agenesis, reduced bronchial branching occurs as early as 12–14 weeks of gestation (i.e. at a time before amniotic fluid is produced by the kidneys), which suggests that a direct renal factor supports lung development. Later, the presence of amniotic fluid is necessary for normal fetal lung development. The fetal lung is a net fluid secretor, the output of fluid reaching as high as 5 ml/kg shortly before birth. Most of the fluid produced within the lungs remains there because of the mechanical effect exerted by amniotic fluid pressure, and normally only a small amount of this fluid contributes to the amniotic fluid. The normal functioning of the kidneys regulates the volume and pressure of the lung airway fluid and may in turn provide the pressure needed for expansion and enlargement of the bronchial and pulmonary systems. Interestingly, obstruction to the fetal airway causes accelerated maturation of alveoli; this approach has been used therapeutically in congenital diaphragmatic hernia, where intermittent inflation and deflation of an intra-tracheal balloon in a lamb model resulted in better lung growth and maturation (Nelson et al 2005).
FUNCTIONAL CHANGES IN THE LUNG AROUND THE TIME OF BIRTH

Just prior to birth, the placenta is the organ of respiration. Virtually all the venous return to the right heart is shunted away from the lungs through the foramen ovale and the ductus arteriosus. Pulmonary vascular resistance (PVR) is maintained at a very high level by the muscular precapillary vessels. At birth, the umbilical cord is tied and cut, and within seconds the lungs must take over all respiratory function in order to maintain life. They also must convert from secreting fluid to absorbing it. The mechanisms that mediate these dramatic changes are obscure. However, it is clear that the first breath results in vasodilatation by at least two mechanisms. First, the mechanical effect of traction on the vasculature: as the chest wall expands, it pulls open the pulmonary vessels. Second, oxygen entering the lungs for the first time produces pulmonary vasodilatation. The experimental demonstration that PVR falls even if the fetus is delivered into an atmosphere of pure nitrogen, implies that other mediators, including cyclo-oxygenase metabolites, are undoubtedly important. The gene for cyclo-oxygenase 1 (but not 2) in endothelium and vascular smooth muscle shows enhanced expression in late fetal and early post-natal life. Endothelin receptor expression increases around the time of birth, implying a role for this system in postnatal adaptation. The role of nitric oxide in postnatal adaptation is controversial, and there are likely to be important species differences. Nitric oxide synthase (NOS) is more abundant in young compared with mature animals, and smooth muscle sensitivity to nitric oxide may be greater at birth than in older animals. The effects of mediators may differ ante- and postnatally, e.g. endothelin (ET)-1 causes vasodilatation in fetal sheep, but vasoconstriction postnatally.

Immediately after birth, and before structural remodeling has taken place, PVR may rise steeply if the baby becomes even minimally hypoxic or acidaemic. The fetal shunts (foramen ovale and ductus arteriosus) reopen and right to left shunting causes profound hypoxemia, 'persistent fetal circulation'.
POSTNATAL LUNG DEVELOPMENT

The amount and type of connective tissue in the lung change after birth. The neonatal lung has abundant Type III and Type IV collagen, but little Type I collagen. Types III and IV collagen are not mechanically strong, suggesting that the neonatal lung has a phenotype that facilitates the changes in cell shape and orientation which characterize adaptation to extrauterine life. It is probable that the rapid deposition of Type I collagen postnataally contributes structural stiffness to the blood vessel walls.

Lung volume increases most rapidly during the first year of life and also increases more rapidly than airway calibre during this time, a finding which is consistent with the concept of dysanaptic lung growth, i.e. a dissociation between the growth of the lung parenchyma and the airways. Most of the alveoli have been formed by two years of age, and subsequent lung growth primarily results from an increase in the size of individual alveoli. Forced vital capacity is reported to be the same in male and female infants and very young children (Jones et al 2000), which is consistent with post mortem morphometric measurements. By the second year of life the rate of increase in forced vital capacity is similar to that reported in older children.

During childhood, lung volumes and flow rates increase linearly with height, with a greater intercept and more positive slope in boys compared to girls (Rosenthal et al 1993a & b). The linearity of these changes is interrupted by puberty, when important shape changes occur in the thorax, particularly in boys, and are mirrored by changes in the size of the underlying lung (and in particular the alveoli) as manifest by an abrupt increase in vital capacity, forced expired volume in one second, and total lung capacity. Thereafter, the change in lung size again proceeds in a linear fashion. High resolution computed tomographic scanning has been used to measure airway dimensions, although this technique should be used with caution because of the radiation exposure. Alveolar size can now be measured using hyperpolarized helium, using magnetic resonance imaging.

Normal postnatal pulmonary arterial development

Immediately after birth, dramatic remodelling of the pulmonary vasculature occurs to effect an abrupt reduction of pulmonary vascular resistance. This process continues at a rapid rate throughout the first 1–2 months, while the lungs adapt to extrauterine life, and then more slowly throughout childhood. Failure to remodel in the presence of an anatomically normal heart leads to persistent pulmonary hypertension. Normal postnatal pulmonary arterial development in the full-term neonate can be divided into three stages:

Stage one
lasts from birth to about postnatal day 4, and concerns the immediate adaptation to extrauterine life. At birth, the endothelial cells of the precapillary arteries are squat and have narrow bases on the subendothelium, a low surface : volume ratio and many surface projections. Five minutes after birth, the endothelial cells are thinner and gradually show less cell overlap, the surface : volume ratio increases, few cell projections are seen, the vessel wall becomes thinner and the lumen diameter increases (Fig. 59.23). The smooth muscle cells show a significant reduction in diameter during this time.

Fig. 59.23 En face views (left) and transverse sections (right) showing the changes in the endothelial and smooth muscle cells of small muscular pulmonary arteries accompanying terminal bronchi from the neonatal period to 3 weeks after birth.
Stage two

lasts from around day 4 to 3–4 weeks, and is the time when the cells deposit matrix around themselves to fix their new positions. At birth, the internal elastic lamina of the small muscular arteries consists only of amorphous elastin in a basal lamina-like matrix. By 3 weeks of age, a definitive elastic lamina is evident, although it is heavily fenestrated, permitting contact between the endothelial cells and the smooth muscle cells.

Stage three

continues into adulthood. The intrapulmonary arteries increase in size and their walls increase in thickness. However, the maturation of all of the pulmonary vascular smooth muscle cells, from the hilum to the precapillary bed, is not advanced until 2 years. As the distal airspaces expand, the capillary nets fuse from one alveolus to another, forming, for a period, an extensive double capillary net: this process can be seen from postnatal day 28, becomes more extensive by 1.5 years, and it is believed to be complete by 5 years.
CONGENITAL MALFORMATIONS OF THE TRACHEA, BRONCHI AND LUNGS

This is an enormous topic and only a small number of abnormalities can be mentioned here (for further information, see Bush 2001; Abel et al 2006). The concept of the lung as six ‘trees’ has been mentioned earlier: all but the systemic venous tree may contribute to a congenital thoracic malformation (CTM). In addition, congenital abnormalities of the heart and great vessels, and of the chest and abdominal walls, including neuromuscular disease, may impact on lung development. It is somewhat artificial to describe airway malformations in isolation, and the possibility of associated vascular abnormalities must always be considered. Moreover, descriptions of what is seen clinically should be kept separate from speculations about the embryological origins of the abnormality.

Disorders of the proximal airways

Tracheomalacia and bronchomalacia

Abnormalities in cartilage development lead to the affected airways being ‘floppy’, and collapsing during inspiration or expiration, depending on whether they are outside or inside the bony thorax, respectively: these abnormalities are termed tracheomalacia when the trachea is affected, and bronchomalacia when the bronchi are involved. The abnormality may involve a small, localized area, or may be more generalized (e.g. Williams–Campbell syndrome – congenital deficiency of the airway cartilage – in which there is diffuse bronchomalacia from the second to the seventh generation of bronchi). Tracheobronchomalacia usually presents in early infancy with cough, tachypnoea, stridor and wheeze; it may also be associated with cardiac or respiratory abnormalities, such as absent pulmonary valve syndrome, or tracheo-oesophageal fistula, respectively. Patients with significant obstruction and apnoea may be treated by the insertion of airway stents if the disease is localized; generalized disease may mandate respiratory support, either with non-invasive mask ventilation during sleep, or via a tracheostomy, depending on severity. Surgical treatment by aortopexy is controversial.

Tracheo-oesophageal fistulae

Tracheo-oesophageal fistulae are the most common abnormalities of the lower respiratory tract, and occur in about 1 in 3000 births. They usually present in the newborn with recurrent respiratory distress and choking spells, although late presentation in adult life has been described. The anomaly may be associated with oesophageal atresia. Normally, the oesophagus lengthens with the rapid elongation of the embryo up to 7 weeks. The rapid proliferation of the oesophageal lumen partially obliterates the mucosa and recanalization is not complete until 8 weeks. The cellular processes that lead to separation of the trachea and oesophagus occasionally produce oesophageal atresia. Tracheo-oesophageal atresia is rare, with an incidence of 1 in 3000 to 1 in 4500 births. Five types of tracheo-oesophageal fistulae may be recognized (Fig. 59.24). In almost all cases, the oesophagus ends blindly and the stomach is connected to the lower end of the trachea. Because of this connection, the abdomen becomes rapidly distended with air once the baby is delivered and starts breathing. Prenatally, polyhydramnios may be a clinical feature, but may not be apparent until the third trimester. In two of the five types of tracheo-oesophageal fistulae there is no communication between the stomach and the upper gut. Such
cases are identifiable on ultrasound, because the stomach should always be visible at a 20-week examination, and its absence on ultrasound should prompt further evaluation.

**Fig. 59.24** Examples of tracheo-oesophageal fistulae and oesophageal atresia.

Tracheo-oesophageal fistula is commonly associated with other congenital anomalies, including cardiovascular defects (30%), anorectal (15%) and genitourinary anomalies (15%). These defects may be combined in the VATER syndrome, which involves vertebral, anorectal, cardiac and oesophageal anomalies, together with radial aplasia and the presence of a single umbilical artery.

**Complete cartilage rings**

The normal large airway cartilages are horseshoe shaped. Complete cartilage rings may develop in the trachea and large airways, and the posterior membranous part of the airway may be absent in a single cartilage or in long segments of the airway. This abnormality may be associated with vascular abnormalities such as pulmonary artery sling (where the left pulmonary artery originates from the right pulmonary artery, and not from the main pulmonary trunk). Extensive severe disease may present with neonatal respiratory distress; later presentations include apparently steroid-resistant asthma. Tracheal transplantation has been used to treat long segment tracheal stenosis.

**Disorders of the distal airways**

**Agenesis and aplasia of the lungs**

Agenesis/aplasia of the lungs are extremely rare congenital abnormalities, in which there may be unilateral or bilateral absence of the lung. In agenesis, the airway stump is absent, i.e. the trachea is absent in bilateral disease, or the primary bronchus is absent in unilateral disease. In aplasia, there is a rudimentary airway stump, but no distal lung; the contralateral lung is enlarged, with a greater number of alveoli, but has a normal bronchial pattern. Individuals with aplasia may present with recurrent infection, dyspnoea and reduced exercise capacity, and there may be pooling of bronchial secretions, with secondary infection and overspill of infected secretions into
the contralateral normal lung.

**Bronchogenic and other cysts**

Cysts of various types, by order of frequency, may be found in the carinal (51%), right para-tracheal (19%), para-oesophageal (14%), hilar (9%) and pericardial, retrosternal and para-vertebral (7%) regions. Clinically they are part of the spectrum of congenital thoracic malformations, and can only be classified in more detail pathologically when the wall of the cyst is examined; they may have a systemic blood supply and venous drainage. Multicystic abnormalities, described as various types of congenital cystic adenomatous malformations (CCAM) and sequestrations (intra- and extra-pulmonary), are best considered generically as CTM spectrum, at least until examined pathologically. Presentation may be with a range of problems, from intractable newborn respiratory distress to a chance finding in adult life. Treatment is usually surgical if feasible, for all but the tiniest malformations.

**Bronchial atresia**

Bronchial atresia is a congenital condition in which a major bronchus or segmental airway ends blindly or with a thin membrane. Pulmonary development normally occurs distally, and over time this tissue becomes distended with debris and mucus (bronchocele), with adjacent over-inflated lung tissue. It characteristically affects the left upper lobe (64% of cases) and the chest radiographic findings are of a perihilar ovoid density with strands projecting into a localized area of hyperlucent lung. The left lower lobe is affected in 14% of cases and the right lower and right middle lobe in 8% of cases. The majority of cases are asymptomatic and are revealed as incidental findings on chest radiographs. However, many eventually become the seat of recurrent infection, and require operative removal. Some infants may show a congenital large hyperlucent pulmonary lobe (CLHL). This condition is termed ‘congenital lobar emphysema’ although it has nothing to do with adult emphysema. Presentation in severe cases is with newborn respiratory distress, in which case early surgery is required, otherwise, it may be a chance radiographic finding later in life, in which case no action is needed.

GENERAL STRUCTURE AND FUNCTION OF THE ABDOMINOPELVIC CAVITY

Although often considered separately, the abdomen and pelvis form the largest effectively continuous visceral cavity of the body. They act together to provide multiple vital functions including: support and protection of the digestive and urinary tracts and internal reproductive organs and their associated neurovascular supplies; transmission of the neurovascular supply to and from the thorax and the lower limb; provision of support and attachment to the external genitalia and access to and from the internal reproductive and urinary organs; provision of accessory muscles of physiological actions such as respiration, defecation, and micturition; support for the spinal column in weight bearing and movement.

MUSCULOSKELETAL FRAMEWORK OF THE ABDOMEN AND PELVIS

The walls of the abdominopelvic cavity consist of five lumbar vertebrae and their intervening intervertebral discs (lying in the posterior midline); three layers of skeletal muscles (transversus abdominis, internal oblique and external oblique) with associated fasciae and skin (lying lateral and anterolateral); a single muscular layer (rectus abdominis) with its associated fascial coverings (lying anterior); the bony ‘bowl’ formed by the walls of the true and false pelvis (ilium, ischium and pubis on each side); the muscles of the pelvic floor and perineum (lying inferiorly); the diaphragm (lying superiorly) (Fig. 60.1).
The bony and muscular structures making up the abdominopelvic ‘cavity’. The anterolateral abdominal muscles have been removed for clarity.

The bony protection of the cavity is restricted to the pelvis (true and false) and the upper abdomen, which is partly enclosed by the anterolateral portions of the lower six ribs and their cartilages even though these structures are technically part of the thoracic wall. Between these two zones, the anterolateral abdominal wall is entirely musculofascial but of sufficient thickness and strength that it provides adequate protection for the viscera.
such that even direct blows can be resisted.

The abdominal wall and retroperitoneal structures play an important role in the function of the spinal column in both movement of the thorax in relation to the pelvis and in aiding support of the spine in weight bearing. The anterolateral muscles provide assistance with flexion and rotation of the thorax in relation to the pelvis (or vice versa if the thorax is fixed).

In the upright position, the pelvis lies at an angle such that the pelvic canal slopes posteriorly at an angle of 45° to the main abdominal visceral cavity. The main abdominal cavity is shaped by the spinal column and the posterior abdominal wall muscles. Although less pronounced than in the thorax, due to the presence of quadratus lumborum and psoas major, its prominence within the abdominal cavity produces two distinct paravertebral gutters on either side of the vertebral column. The lordosis of the lumbar spine in combination with the angle between the fifth lumbar vertebra and the sacrum produces the parabola shape of the sagittal section of each paravertebral gutter.

**Thoracoabdominal interface**

The thoracic and abdominal cavities interface with each other across the diaphragm. Six principle communications exist between the two cavities: the inferior vena cava, as it crosses between its short supra-hepatic portion and the intrathoracic portion below the right atrium, through the caval opening of the diaphragm (Ch. 62); the oesophagus passing inferiorly through the oesophageal opening of the diaphragm (Ch. 65); the aorta between the descending thoracic and abdominal portions, posterior to the median arcuate ligament of the diaphragm (Ch. 62); the lymphatics of the abdomen draining upwards to the thorax, mainly posterior to the median arcuate ligament via the thoracic duct lying posterolateral to the aorta, but also via peri-caval lymphatics and small vessels draining directly through and at the peripheral insertions of the diaphragm; the azygos and hemiazygos veins ascending behind the median arcuate ligament of the diaphragm into the thoracic azygos system (Ch. 62); the autonomic nervous system, both sympathetic and parasympathetic (see below) which cross between the two cavities behind the medial arcuate ligaments of the diaphragm, via the various diaphragmatic openings, and directly through the substance of the diaphragm itself (Ch. 54). Cutaneous neurovascular structures also cross between the thorax into the abdominal wall structures.

**Pelvis–lower limb interface**

The pelvis forms an integral part of the bony structure of both the abdominopelvic cavity and the lower limb. It transmits the weight of the upright body from the femoral heads to the lumbar spine as well as providing a stable platform about which movement of the hip joint can occur. Its bony
surfaces give rise to extensive muscular attachments for the muscles of the buttock and thigh (Ch. 67) as well as for the muscles of the pelvic floor and perineal diaphragm (Ch. 63). The pelvis also transmits or gives origin to the neuro-lympho-vascular structures which supply the lower limb. The principle structures are as follows. The venous drainage includes the common femoral vein passing under the inguinal ligament to become the external iliac vein; the obturator veins passing through the obturator foramen; the superior and inferior gluteal veins draining from the buttock into the internal iliac vein via the greater and lesser sciatic foramina; multiple smaller venous channels. The arterial supply includes the external iliac artery passing under the inguinal ligament to become the common femoral artery; the obturator artery passing into the thigh via the obturator foramen; the superior and inferior gluteal arteries from the posterior division of the internal iliac artery passing out of the pelvis via the greater and lesser sciatic foramina. The lymphatic drainage principally passes under the inguinal ligament, via the femoral and obturator canals and via the sciatic foramina, to drain into the pelvic lymphatic chains (Ch. 63). The somatic neural structures include the femoral, obturator and sciatic nerves and other minor branches of the lumbosacral plexus (Ch. 62). The autonomic neural structures include those running with the arterial supply and with the branches of the lumbosacral plexus. Cutaneous neurovascular structures also cross between the lower abdomen and pelvis into the skin and superficial tissues of the lower limb.
GENERAL ARRANGEMENT OF ABDOMINOPELVIC NEUROVASCULAR STRUCTURES

It is useful to review here the overall arrangement of the neurovascular systems which cover several regions or multiple viscera of the abdominopelvic region. Descriptions of the neurovascular supply to individual organs are given in the relevant chapters.

AUTONOMIC SUPPLY

The autonomic supply to the abdominal and pelvic viscera is via the abdominopelvic part of the sympathetic chain and the greater, lesser and least splanchnic nerves (sympathetic), and the vagus and pelvic parasympathetic nerves (parasympathetic). Considerable ramification occurs between plexuses and ganglia, particularly in the major plexuses around the abdominal aorta, hence the descriptions tend to be simplifications based on the ‘main’ supply to each organ (Fig. 60.2). The details of the terminations of these fibres are given on page 1050.
The cell bodies of neurones of the sympathetic supply of the abdomen and pelvis lie in the intermediolateral grey matter of the first to 12th thoracic and first two lumbar spinal segments. These neurones give rise to myelinated axons which travel in the ventral ramus of the spinal nerve of the same level, leaving it via the white ramus communicans to enter a thoracic or lumbar paravertebral ganglion. Visceral branches may exit at the same level or ascend or descend several levels before exiting but leave the ganglia without synapsing in medial (visceral) branches. These give rise to the greater, lesser and least splanchnic nerves, and the lumbar and sacral splanchnic nerves. Axons destined for supply to somatic structures always synapse in the ganglion of the same level and post-ganglionic, unmyelinated axons leave the ganglion via the grey ramus communicans to enter the spinal nerve of the same level.

**Greater splanchnic nerve**

The greater splanchnic nerve is derived from the medial, visceral branches of the fifth to ninth thoracic ganglia. It enters the abdomen running through the fibres of the ipsilateral crus of the diaphragm and lies on the crus as it runs anteroinferiorly. The main trunk of the nerve enters the superior aspect of the coeliac ganglion.

**Lesser splanchnic nerve**

The lesser splanchnic nerve is derived from the medial, visceral branches of the 10th and 11th thoracic ganglia. It enters the abdomen running through the lowermost fibres of the ipsilateral crus of the diaphragm or under the medial arcuate ligament and lies on the crus as it runs anteroinferiorly. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It occasionally joins the greater and least splanchnic nerves as a single splanchnic nerve.

**Least splanchnic nerve**

The least splanchnic nerve is derived from the medial, visceral branches of the 12th thoracic ganglia. It enters the abdomen running with the sympathetic chain under the medial arcuate ligament and runs inferiorly to enter the renal plexus. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It is sometimes part of the lesser splanchnic nerve, when it forms a twig which enters the renal plexus just below the aorticorenal ganglion.

**Lumbar sympathetic system**

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia. The trunk runs in the extraperitoneal connective tissue anterior to the vertebral column and along the medial margin of psoas major. Superiorly, it is continuous with the thoracic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac artery and is continuous with the pelvic sympathetic trunk. On the right side, it lies posterior to inferior vena cava, and on the
left it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels, but may pass behind some lumbar veins.

The first, second and sometimes third lumbar ventral spinal rami send white rami communicantes to the corresponding ganglia. Grey rami communicantes pass from all four lumbar ganglia to the lumbar spinal nerves. They are long, and accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which psoas major is attached. They supply the sympathetic innervation to the lumbar somatomes via these arteries. Four lumbar splanchnic nerves pass as medial branches from the ganglia to join the coeliac, inferior mesenteric (or occasionally abdominal aortic) and superior hypogastric plexuses. The first lumbar splanchnic nerve, from the first ganglion, gives branches to the coeliac, renal and inferior mesenteric plexuses. The second nerve joins the inferior part of the intermesenteric or inferior mesenteric plexus. The third nerve arises from the third or fourth ganglion and passes anterior to the common iliac vessels to join the superior hypogastric plexus. The fourth lumbar splanchnic nerve from the lowest ganglion passes above the common iliac vessels to join the lower part of the superior hypogastric plexus, or the inferior hypogastric 'nerve'.

Vascular branches

Vascular branches from all the lumbar ganglia join the abdominal aortic plexus. Fibres of the lower lumbar splanchnic nerves pass to the common iliac arteries and form a plexus which extends along the internal and external iliac arteries. Many postganglionic fibres travel in the muscular, cutaneous and saphenous branches of the femoral nerve, supplying vasoconstrictor nerves to the femoral artery and its branches in the thigh. Other postganglionic fibres travel via the obturator nerve to the obturator artery. Considerable uncertainty persists regarding the exact path of the sympathetic nerve supply to the lower limb (Pick 1970). Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and the intervening parts of the sympathetic trunk; very rarely, this procedure is useful in treating vascular insufficiency of the lower limb.

Pelvic sympathetic system

The pelvic sympathetic trunk lies in the extraperitoneal tissue anterior to the sacrum beneath the presacral fascia. It lies medial or anterior to the anterior sacral foramina and has four or five interconnected sacral ganglia (they often merge to a greater or lesser extent). Above, it is continuous with the lumbar sympathetic trunk and receives preganglionic fibres descending via the lumbar chain from the lower lumbar spinal segments. Below the lowest ganglia, the two trunks converge to unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to the sacral and coccygeal spinal nerves but there are no white rami communicantes. Medial branches connect across the midline and twigs from the first two ganglia, referred to as sacral splanchnic nerves, join the inferior hypogastric plexus or the hypogastric 'nerve' to be distributed to the pelvic viscera via a fine network of pelvic nerves (the 'pelvic plexus'). Small branches form a plexus on the median sacral artery.

Vascular branches

Postganglionic fibres pass through the grey rami communicantes to the roots of the
sacral plexus. Those forming the tibial nerve are conveyed to the popliteal artery and its branches in the leg and foot whilst those in the pudendal and superior and inferior gluteal nerves accompany the same named arteries to the gluteal and perineal tissues. Branches may also supply the pelvic lymph nodes.

Preganglionic fibres for the rest of the lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia.

**Parasympathetic innervation**

The parasympathetic neurones innervating the abdomen and pelvis lie either in the dorsal motor nucleus of the vagus nerve or in the intermediolateral grey matter of the second, third and fourth sacral spinal segments. The vagus nerves supply parasympathetic innervation to the abdominal viscera with the exception of the colon distal to the mid descending colon, rectum and upper anal canal. The nerves are derived from the oesophageal plexus and enter the abdomen via the oesophageal opening, closely related to the anterior and posterior walls of the abdominal oesophagus, from which they are separated by loose connective tissue. The anterior vagus is mostly derived from the left vagus and the posterior from the right vagus. The nerves supply the intra-abdominal oesophagus and stomach directly. The anterior nerve supplies branches to the hepatic plexus, which innervates the liver parenchyma and vasculature, the biliary tree including the gallbladder, and the structures in the free edge of the lesser omentum. The posterior nerve supplies branches to the coeliac plexus. These fibres frequently constitute the largest portion of the fibres derived from the plexus: they arise directly from the nerve and from the greater posterior gastric nerve and run beneath the peritoneum, deep to the posterior wall of the lesser sac, at the upper limit of the lesser omentum to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach's) and submucosal (Meissner's) plexuses (see below).

**Pelvic splanchnic nerves**

Pelvic splanchnic nerves to the pelvic viscera travel in anterior rami of the second, third and fourth sacral spinal nerves. They leave the nerves as they exit the anterior sacral foramina and pass in the presacral tissue as a fine network of branches which are distributed to three locations. Most pass anterolaterally into the network which forms the inferior hypogastric plexus, whence most are distributed as a fine network of nerves (the 'pelvic plexus') to the pelvic viscera (alongside the sympathetic pelvic supply). Some join directly with the fibres forming the inferior hypogastric nerves and hence ascend out of the pelvis, some as far as the superior hypogastric plexus. A few run superolaterally in the presacral tissue, over the pelvic brim anterior to the iliac vessels. They pass directly into the tissue of the retroperitoneum and into the posterior aspect of the mesentery of the sigmoid and descending colon.

The pelvic splanchnic nerves are motor to the smooth muscle of the rectum, anus and bladder wall but inhibitory to the vesical sphincter. They supply vasodilator fibres to the erectile tissue of the penis and clitoris and are probably also vasodilator to the testes, ovaries, uterine tubes and uterus. They are visceromotor to the sigmoid and descending colon as far as the splenic flexure and distal transverse colon.
Abdominopelvic autonomic plexuses and ganglia

The abdominopelvic autonomic plexuses are somewhat variable and often fuse or are closely inter-related. The following descriptions recognize their main features (Figs 60.3, 60.4).

Fig. 60.3  The autonomic plexuses innervating the abdominal and pelvic viscera: schematic diagram.
Coeliac plexus

The coeliac plexus is the largest major autonomic plexus, sited at the level of the twelfth thoracic and first lumbar vertebrae. It is a dense network uniting two large coeliac ganglia and surrounds the coeliac artery and the root of the superior mesenteric artery. It is posterior to the stomach and lesser sac, anterior to the crura of the diaphragm and the beginning of the abdominal aorta, and lies between the suprarenal glands. The plexus and ganglia are joined by the greater and lesser splanchnic nerves and branches from the vagus and phrenic nerves. The plexus extends as numerous secondary plexuses along adjacent arteries. The coeliac plexus is connected to, or gives rise to, the phrenic, splenic, hepatic, superior mesenteric, suprarenal, renal and gonadal plexuses (Fig. 60.5).

Coeliac and aorticorenal ganglia

The coeliac ganglia are irregular masses on each side of the coeliac trunk adjacent to the suprarenal glands and anterior to the crura of the diaphragm. The right ganglion is posterior to the inferior vena cava, the left ganglion posterior to the origin of the splenic artery. The ipsilateral greater splanchnic nerve joins the upper part of each ganglion. The lower part of each ganglion forms a distinct subdivision, usually termed the aorticorenal ganglion, which receives the ipsilateral lesser splanchnic nerve and gives origin to the majority of the renal plexus (which most commonly lies anterior to the origin of the renal artery).
Phrenic plexus

The phrenic plexus lies around the inferior phrenic arteries on the crura of the diaphragm. It arises as a superior extension of the coeliac ganglion and often receives one or two sensory branches from the phrenic nerve. The left phrenic plexus is usually larger than the right. On the left it supplies branches to the left suprarenal gland and the cardiac orifice of the stomach. The right phrenic plexus joins the phrenic nerve, forming a small phrenic ganglion which distributes branches to the inferior vena cava, suprarenal gland and hepatic plexus.

Superior mesenteric plexus and ganglion

The superior mesenteric plexus lies in the preaortic connective tissue posterior to the pancreas, around the origin of the superior mesenteric artery. It is an inferior continuation of the coeliac plexus, and includes branches from the posterior vagus nerve and the coeliac plexus. Its branches accompany the superior mesenteric artery and divide into secondary plexuses which are distributed along the branches of the artery. The superior mesenteric ganglion lies superiorly in the plexus, usually above the origin of the superior mesenteric artery.

Abdominal aortic plexus (intermesenteric plexus)

The abdominal aortic plexus lies on the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. It consists of 4–12 intermesenteric nerves, connected by oblique branches. It is continuous above with the superior mesenteric plexus and below with the superior hypogastric plexus, and is formed by parasympathetic and sympathetic branches from the coeliac plexus. It receives rami from the first and second lumbar splanchnic nerves (which contain sympathetic fibres). The abdominal aortic plexus is connected to the gonadal, inferior mesenteric, iliac and superior hypogastric plexuses.

Inferior mesenteric plexus

The inferior mesenteric plexus lies around the origin of the inferior mesenteric artery and is distributed along its branches. It is formed predominantly from the aortic plexus and the first and second lumbar splanchnic nerves (sympathetic fibres), but it also receives connections from the superior hypogastric plexus (sympathetic and parasympathetic fibres). Disruption of the intermesenteric and inferior mesenteric plexuses rarely causes clinically significant disturbances of autonomic function.

Superior hypogastric plexus

The superior hypogastric plexus lies anterior to the aortic bifurcation, the left common iliac vein, medial sacral vessels, fifth lumbar vertebral body and sacral promontory, and between the common iliac arteries. It is occasionally termed the presacral nerve, but is seldom a single nerve and it is prelumbar rather than presacral. Most frequently found to the left side of the midline, it lies in extraperitoneal connective tissue from which the parietal peritoneum can easily be stripped. The breadth and condensation of its constituent nerves vary. The attachment of the sigmoid mesocolon and upper limit of the mesorectum containing the superior rectal vessels are anterior and to the left of the lower part of the plexus, and separated from it only by a thin sheet of loose connective tissue. The plexus is formed by branches from the aortic plexus and the
third and fourth lumbar splanchnic nerves (which are mainly sympathetic). It may also contain parasympathetic fibres from the pelvic splanchnic nerves, which ascend from the two inferior hypogastric plexuses, via a series of filaments which are sometimes identified as the right and left hypogastric ‘nerves’. The latter lie in loose connective tissue just posterolateral to the start of the mesorectum and pass over the pelvic brim medial to the internal iliac vessels. The superior hypogastric plexus supplies fibres to the inferior mesenteric plexus and to the ureteric, gonadal and common iliac plexuses as well as small branches which turn abruptly forward into the upper mesorectum to supply the plexus around the superior rectal artery.

**Inferior hypogastric plexus, pelvic plexus and nerves**

The inferior hypogastric plexus lies in the thin extraperitoneal connective tissue on the pelvic side-wall anterolateral to the mesorectal fascia. It is directly related to the internal iliac vessels and the attachments of levator ani, coccygeus and obturator internus which lie laterally and the superior vesical and obliterated umbilical arteries superiorly. In males, the inferior hypogastric plexus lies posterolaterally on either side of the seminal vesicles, prostate and the posterior part of the urinary bladder. In females, each plexus lies lateral to the uterine cervix, vaginal fornix and the posterior part of the urinary bladder, and often extends into the broad ligaments of the uterus.

The inferior hypogastric plexus is formed mainly from the sacral splanchnic (sympathetic) and pelvic splanchnic (parasympathetic) branches; a small contribution is made from some sympathetic fibres (from the lower lumbar ganglia) which descend into the plexus via the inferior hypogastric nerves from the superior hypogastric plexus. It gives origin to a complex network of tiny pelvic branches, often referred to as the ‘pelvic plexus’, which supply the pelvic viscera either directly or via periarterial plexuses. The branches of the pelvic plexus supply the vas deferens, seminal vesicles, prostate, accessory glands and penis in males, the ovary, fallopian tubes, uterus, uterine cervix and vagina in females, and the urinary bladder and distal ureter in both sexes. The plexus also gives rise to the long branches of the parasympathetic pelvic splanchnic nerves.

**Inferior hypogastric nerves**

The inferior hypogastric ‘nerves’ are often double, multiple or form an extended plexus on each side. They contain mainly sympathetic and a few parasympathetic fibres. Most of these fibres are ascending from the inferior hypogastric plexus and so it is better to describe them running up out of the pelvis than down into it.

**Other plexuses**

Separate plexuses exist for organs within the abdomen and pelvis, for example, the hepatic, splenic and gonadal plexuses. Each tends to lie around the main arterial supply to the organ and is supplied with both sympathetic and parasympathetic fibres from one or more of the main plexuses.

**Para-aortic bodies**

The para-aortic bodies are condensations of chromaffin tissue which are found in close relation to the aortic autonomic plexuses and lumbar sympathetic chains. They are largest in the fetus, become relatively smaller in childhood and have largely
disappeared by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the aorta in the region of the intermesenteric, inferior mesenteric and superior hypogastric plexuses. They may lie as high as the coeliac plexus, as low as the inferior hypogastric plexus in the pelvis, or may be closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells which persist into adulthood may, rarely, be the sites of development of a tumour of chromaffin tissue (phaeochromocytoma); these are much more commonly found arising from the cells of the suprarenal medulla. The wide variation in the site of persistent para-aortic body tissue accounts for the range of locations of such tumours.
MAJOR ABDOMINOPELVIC ARTERIAL AND VENOUS ARRANGEMENTS

The major vessels which occupy the abdomen and pelvis not only supply the viscera, retroperitoneal structures and much of the bony and soft tissue walls of the cavities, they also course through the cavities en route to supply the lower limbs. Both the arterial and systemic venous trees of the abdomen and pelvis lie predominantly posteriorly in the abdomen and postero-laterally in the pelvis; from the caval and aortic orifices in the diaphragm and the other points where smaller vessels cross the abdominothoracic interface, they follow the general parabolic shape of the lumbar spine. The pelvic divisions follow the contours of the brim and side wall of the true pelvis (Figs 60.6, 60.7). The individual parts of the aorto-iliac and iliocaval systems are described in the appropriate chapters.
Fig. 60.6 The overall arrangement of the aorto-iliac arterial tree of the abdomen and pelvis.
Fig. 60.7 The overall arrangement of the iliocaval venous system of the abdomen and pelvis.

**Arterial supply to the gastrointestinal tract**

The arterial supply to the gastrointestinal tract is derived from the anterior midline visceral branches of the aorta. There are usually three anterior branches, the coeliac trunk and the superior and inferior mesenteric arteries. Variants in the origin of the arteries are very rare. The most common is a joint
origin of the upper two branches as either a coeliacomesenteric trunk or a lienoohepaticomesenteric trunk with a separate left gastric artery. Accessory or replaced branches to the upper abdominal viscera are more common (see Chs 65, 66, 67 and 68). Accessory anastomotic vessels between the origin of the coeliac trunk and superior mesenteric artery are rare. The inferior mesenteric artery always arises separately, however, replaced, accessory or anastomotic vessels occasionally arise from the proximal superior mesenteric artery or its branches and contribute to the arterial supply to the proximal territory of the inferior mesenteric artery.

The coeliac trunk and its branches supplies the gastrointestinal tract from the distal third of the oesophagus to the mid part of the duodenum and all derived adenexae (liver, biliary tree, spleen, dorsal pancreas, greater omentum and lesser omentum). The superior mesenteric artery supplies the tract from the mid second part of the duodenum to the distal third of the transverse colon (jejunum, ileum, caecum, appendix, ascending colon and ileal mesentery). The inferior mesenteric artery supplies the tract from the distal transverse colon to the upper anal canal. Other than accessory arteries, numerous medium calibre arteries form anastomoses between the vascular territories. The most profuse occurs around the head of the pancreas and the duodenum, where anastomoses form between the anterior and posterior superior pancreaticoduodenal arteries and the inferior pancreaticoduodenal arteries; the posterior superior pancreaticoduodenal artery and jejunal arteries; the greater pancreatic artery and jejunal arteries. The anastomoses between the territories of the superior and inferior mesenteric arteries are less pronounced and more variable: the most reliable is the pericolic marginal artery, which runs along the transverse colon. Additional anastomotic arcades may exist in the colic mesentery between the transverse and descending colon.

**Portal venous system**

The (hepatic) portal system, like all portal venous systems, connects two capillary beds: that of the abdominal part of the digestive tube, with the exception of the lower anal canal but including the abdominal part of the oesophagus, and all organs, except the liver, derived from it (i.e. the spleen, pancreas and gallbladder) and the hepatic sinusoidal ‘capillary’ bed. The intrahepatic portal vein ramifies like an artery, and ends in sinusoids from which vessels again converge to reach the inferior vena cava via the hepatic veins. In adults, the portal vein and its tributaries have no valves. In fetal life and for a short postnatal period, valves are demonstrable in its tributaries, but they usually atrophy; although some occasionally persist in an atrophic form into adulthood.

**Portal vein**
The portal vein begins at the level of the second lumbar vertebra and is formed from the convergence of the superior mesenteric and splenic veins (see Fig. 70.8). It is approximately 8 cm long and lies anterior to the inferior vena cava, posterior to the neck of the pancreas (Fig. 60.8) and obliquely to the right. It ascends behind the first part of the duodenum, the common bile duct and gastroduodenal artery. At this point it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum, ascends anterior to the epiploic foramen to reach the right end of the porta hepatis, and then divides into right and left main branches which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum it lies posterior to both the common bile duct and hepatic artery. The portal vein is surrounded by the hepatic nerve plexus and accompanied by many lymph vessels and some lymph nodes.
Tributaries of the portal vein

The right branch of the portal vein usually receives the cystic vein and then enters the right lobe of the liver. The left branch receives only the obliterated umbilical vein via the ligamentum teres which connects to its vertical portion. The main extrahepatic tributaries of the main portal vein are the coronary or the left gastric vein which ends in the left margin of the portal vein, and the
posterior superior pancreaticoduodenal vein nearer to the head of the pancreas.
GENERAL MICROSTRUCTURE OF THE GUT WALL

The gut wall displays a common structural plan which is modified regionally to take account of local functional differences. The general microstructure is best appreciated by reference to the development of the gut (Ch. 73). Much of the alimentary canal originates as a tube of endoderm enclosed in splanchnopleuric mesoderm. Its external surface faces the embryonic coelom, and the endodermal lining forms the epithelium of the canal and also the secretory and ductal cells of various glands which secrete into the lumen, including the pancreas and liver. The splanchnopleuric mesoderm forms the connective tissue, muscle layers, blood vessels and lymphatics of the wall, and its external surface becomes the visceral mesothelium or serosa. There is no serosa surrounding the cervical and thoracic portions of the gut, or where the hindgut traverses the pelvic floor: in these sites the gut tube is surrounded by a connective tissue adventitia. Neural elements invade the gut from neural crest tissue (Ch. 24). The smooth muscle of the muscularis externa layers of the alimentary canal is supplemented with striated muscle both cranially (from the branchial arches) and caudally. The mature gut wall has four main layers, namely mucosa, submucosa, muscularis externa and serosa (Fig. 60.9). The mucosa (mucous membrane) is the innermost layer and is subdivided into a lining epithelium, an underlying lamina propria (a layer of loose connective tissue, where many of the glands are also found) and a thin layer of smooth muscle, the muscularis mucosae. The submucosa is a strong and highly vascularized layer of connective tissue. The muscularis externa consists of inner circular and outer longitudinal layers which are present throughout the gut wall: a partial oblique layer is present only in the stomach. The external surface is bounded by a serosa or adventitia, depending on its position within the body.
The epithelium is a protective barrier and the site of secretion and absorption. Its protective function (against mechanical, thermal and chemical injury) is particularly evident in the oesophagus and in the terminal part of the rectum, where it is thick, stratified, and covered in mucus, which serves as a protective lubricant. Other than in these sites, the epithelium lining the gut wall is single-layered, and either cuboidal (in glands) or columnar. It contains cells modified for absorption as well as various types of secretory cell.

The barrier function and selectivity of absorption depend on tight junctions over the entire epithelium. The surface area of the lumen available for secretion or absorption is increased by the presence of mucosal folds, pits, crypts, villi and glands (Fig. 60.9). Microvilli on the surfaces of individual absorptive cells amplify the area of apical plasma membrane in contact with the contents of the gut. Some
glands lie in the lamina propria, some in the submucosa, and others (the liver and pancreas) are totally external to the wall of the gut. All of these glands drain into the lumen of the gut through individual ducts. The epithelium also contains scattered neuroendocrine (enteroendocrine) cells.

**Lamina propria**

The lamina propria consists of compact connective tissue, often rich in elastin fibres, which supports the surface epithelium and provides nutrient vessels and lymphatics. Lymphoid follicles are present in many regions of the gut, most notably in Peyer's patches. Cells within the lamina propria are the source of growth factors which regulate cell turnover, differentiation and repair in the overlying epithelium.

**Muscularis mucosae**

The muscularis mucosae is well developed in the oesophagus and in the large intestine, especially in the terminal part of the rectum. In addition, single muscle cells originating from the muscularis mucosae are found inside the villi or between the tubular glands of the stomach and large intestine. By its contraction, the muscularis mucosae can alter the surface configuration of the mucosa locally, allowing it to adapt to the shapes and mechanical forces imposed by the contents of the lumen, and in the intestinal villi, promoting vascular exchange and lymphatic drainage.

**Submucosa**

The submucosa contains large bundles of collagen and is the strongest layer of the gut wall. However, it is also pliable and deformable and can therefore adjust to changes in the length and diameter of the gut. It contains the largest arterial network of the wall, which supplies both the mucosa and the muscle coat. The submucosa invades the folds which project into the lumen of the oesophagus and rectum, the rugae of the gastric wall, and the plicae circulares of the small intestine, but does not enter the villi.

**Muscularis externa**

The muscularis externa usually consists of distinct inner circular and outer longitudinal layers whose antagonistic activities create waves of peristalsis responsible for the movement of ingested material through the lumen of the gut. In the stomach, where movements are more complex, there is a partial oblique layer, internal to the other two layers. The layer of circular muscle is invariably thicker than the longitudinal muscle, except in the colon, where the longitudinal muscle is gathered into three cords (taenia coli).

The muscularis externa is composed almost exclusively of smooth muscle, except in the upper oesophagus, where smooth muscle blends with striated muscle. Although the oesophageal musculature resembles that of the pharynx, it is entirely under involuntary control. For most of its length, the smooth muscle of the gut wall consists of ill-defined bundles of cells, typically visceral in type, and somewhat larger than vascular smooth muscle cells. They are approximately 500 µm long,
regardless of body size, and are electrically and mechanically coupled. Their fasciculi lack a perimysium, but have sharp boundaries.

The arrangement of the musculature means that a segment of gut can change extensively in diameter (to virtual occlusion of the lumen) and also in length, although elongation is limited by the presence of mesenteries. The co-ordinated activity of the two muscle layers produces a characteristic motor behaviour which is mainly propulsive and directed anally (peristalsis), combined with a non-propulsive motor activity which either mixes the luminal contents, as occurs in the stomach, or partitions them, as occurs at the pyloric sphincter. The muscle maintains constant volume, so that shortening of a segment of the gut wall is accompanied by an increase in muscle layer circumference.

Intestinal smooth muscle exhibits variable and changing degrees of contraction on which rhythmic (or phasic) contractions are superimposed. Slow waves of rhythmic electrical activity, driven by changes in membrane potential in pacemaker cells (interstitial cells), spread throughout the thickness of the circular and longitudinal smooth muscle coats. After spreading circumferentially, slow waves can move in either oral or anal directions, causing segmental contraction. The distances of propagation and the patterns of this spontaneous activity vary between areas of the intestine. Neural regulation of slow and phasic contractions involves excitatory and inhibitory transmitters which are released from the myenteric plexus. This motor control is closely co-ordinated with mucosal absorption and secretion and is mediated via intrinsic nerves in the submucous plexus. The peristaltic reflex occurs during passage of luminal contents down the intestine. It involves ascending contraction and descending relaxation: the sensory limb is mediated by sensory neurones that respond to either mucosal stimulation (intrinsic primary afferents) or muscle stretch (extrinsic afferents).

**Interstitial cells**

Interstitial cells (of Cajal) are thought to act as pacemakers for the myogenic contraction of muscularis externa, establishing the rhythm of bowel contractions through their influence on electrical slow wave activity. They receive modulatory inputs from the enteric nervous system and from the extrinsic innervation of the gut.

Interstitial cells are thin, flat, and branched. They resemble smooth muscle cells because they contain actin and myosin filaments, and are linked by gap junctions to typical smooth muscle cells. However, they are phenotypically distinct from muscle cells because their intermediate filaments are vimentin rather than desmin, (which is typical of muscle cells). They lie in close apposition to varicose nerve endings of at least two types; one contains small, round clear vesicles (50 nm diameter), the other contains flat, discoidal vesicles (70 nm diameter).

The positions of the interstitial cell layers vary regionally. In general, they lie in the same layers as the enteric plexuses. They are scattered among the cells of the circular muscle layer in the oesophagus and stomach, lie between the inner and outer layers of circular smooth muscle in the small intestine, and colocalize with the myenteric plexus and the single layer of the submucosal plexus on the luminal side of the circular component of the muscularis externa, in the large intestine.
Serosa and adventitia

A layer of connective tissue, of variable thickness, lies external to the muscularis externa. In many places it contains adipose tissue. Where the gut is covered by visceral peritoneum, the external layer is a serosa, which consists of a thin connective tissue layer and an external coat of mesothelium. Elsewhere the connective tissue blends with that of the surrounding fasciae and is referred to as an adventitia. Where the alimentary tract is retroperitoneal, the surface facing the abdominal cavity is covered by serosa, and the other parts are covered by adventitia.

Vascular plexuses

Vascular plexuses are present at various levels of the wall, especially in the submucosa and mucosa: they connect with plexuses of vessels which supply the surrounding tissues or those entering through the mesentery, and accompany the ducts of outlying glands.

Innervation

The gut is densely innervated by the autonomic and enteric nervous systems, and is under extrinsic and intrinsic neuronal control. Neuronal cell bodies of the enteric nervous system lie between the circular and longitudinal components of the muscularis externa (myenteric plexus) and within the submucosa (submucosal plexus). They provide the intrinsic sensory and motor supply of the gut wall and connect with extrinsic sensory, motor and sensorimotor nerves of cranial or spinal origin.

Extrinsic innervation

The extrinsic innervation is derived from neurones outside the gut, and contains functional components from the sympathetic, parasympathetic and visceral sensory divisions of the peripheral nervous system (see p. 1041). Visceral sensory endings respond to excessive muscular contraction or distension: their cell bodies are situated in the nodose ganglion of the vagus nerve and in thoracic and lumbar spinal or dorsal root ganglia. The cell bodies of parasympathetic efferent axons lie in the vagal dorsal motor nucleus in the medulla oblongata. Sympathetic efferent fibres arise from the thoracic and lumbar spinal cord and relay in prevertebral sympathetic ganglia (coeliac, mesenteric and pelvic).

A subserosal plexus, which sometimes contains neuronal cell bodies, connects the extrinsic nerve fibres with the myenteric plexus and is particularly prominent near the mesentery. Fibres from this plexus run through the longitudinal muscle layer to reach the myenteric plexus.

Intrinsic innervation

The intrinsic innervation of the gut wall is derived from neurones which are located entirely within the wall in intramural ganglionated plexuses. The myenteric (Auerbach's) plexus is a network of fine bundles of axons and small ganglia which
lies within the muscularis externa, between the circular and longitudinal layers. It is often associated with secondary and tertiary plexuses of nerve fibres which sometimes contain isolated neuronal cell bodies. There are two or more submucosal plexuses, the most superficial of which is Meissner's plexus.

Non-ganglionated nerve plexuses lie at various levels in the wall, notably in the lamina propria (mucosal plexus); at the interface between the submucosa and muscularis externa; between the circular and longitudinal muscles (the non-ganglionated part of the myenteric plexus); and within the serosa. An additional non-ganglionated plexus lies between the internal and external components of the circular muscle of the small intestine. All parts of the myenteric plexus are continuous not only with each other, but also with the nerve fibre bundles in the circular muscle. The latter are connected to the ganglionated and non-ganglionated plexuses of the submucosa, and these in turn are connected with the mucosal plexus by fibres which pass through the muscularis mucosa.
SURFACE AND DIAGNOSTIC ANATOMY OF THE ABDOMEN AND PELVIS

ABDOMINAL PLANES AND REGIONS

For descriptive purposes, the abdomen can be divided by a number of imaginary horizontal and vertical lines drawn using the skeletal landmarks of the thorax and abdomen (Fig.). Projection of these lines into the sagittal or transverse planes can then be used to define certain abdominal 'planes'. Apart from dividing the abdomen into different regions for descriptive purposes, these planes are also of value in defining approximate vertebral levels and the positions of some relatively fixed intra-abdominal structures.

**Vertical planes**

In addition to the midline, which passes through the xiphisternal process and the pubic symphysis, there are two paramedian planes which are projected from the midclavicular line (also sometimes called the lateral or the mammary line). This line passes through the midpoint of the clavicle, crosses the costal margin just lateral to the tip of the ninth costal cartilage, and passes through a point mid way between the anterior superior iliac spine and the symphysis pubis. It approximates to, but does not exactly correspond to, the lateral border of rectus abdominis.

**Horizontal planes**

Several horizontal planes have been defined, but only the subcostal and transtubercular planes are in common clinical use.

The xiphisternal plane runs horizontally through the xiphoid processes at the level of the ninth thoracic vertebra. It demarcates the level of the cardiac plateau on the central part of the upper border of the liver.
The transpyloric plane lies midway between the suprasternal notch of the manubrium and the upper border of the pubic symphysis. It usually lies at the level of the body of the first lumbar vertebra near its lower border and meets the costal margins at the tips of the ninth costal cartilages, where a distinct 'step' may be felt at the costal margin. The linea semilunaris crosses the costal margin on the transpyloric plane. The hilum of both kidneys, the origin of the superior mesenteric artery, the termination of the spinal cord, the neck, adjacent body and head of the pancreas, and the confluence of the superior mesenteric and splenic veins as they form the hepatic portal vein may all lie in this plane. The pylorus may be found in the transpyloric plane, but is not a constant feature.

The subcostal plane is a line joining the lowest point of the costal margins, formed by the tenth costal cartilage on each side. It usually lies at the level of the body of the third lumbar vertebra, the origin of the inferior mesenteric artery from the aorta,
and the third part of the duodenum, although this varies with posture.

The supracristal plane joins the highest point of the iliac crest on each side. It usually lies at the level of the body of the fourth lumbar vertebra, and marks the level of bifurcation of the abdominal aorta. On the posterior abdominal surface, it is a common level for the identification of the fourth lumbar vertebra, and is used to perform lumbar puncture at the L4–5 or L5–S1 intervertebral level, which is safely below the termination of the spinal cord.

The transtubercular plane joins the tubercles of the iliac crests and usually lies at the level of the body of the fifth lumbar vertebra near its upper border. It indicates, or is just above, the confluence of the common iliac veins and marks the origin of the inferior vena cava.

The interspinous plane joins the centres of the anterior superior spines of the iliac crests. It passes through either the lumbosacral disc, or the sacral promontory, or just below them, depending on the degree of lumbar lordosis, sacral inclination and curvature.

The plane of the pubic crest lies at the level of the inferior end of the sacrum or part of the coccyx, depending on the degree of lumbar lordosis, sacral inclination and curvature.

**Abdominal regions**

The abdomen can be divided into nine arbitrary regions by the subcostal and transtubercular planes and the two midclavicular planes projected onto the surface of the body. These regions are used in practice for descriptive localization of the position of a mass or the localization of a patient's pain, and may also be used in the description of the location of the abdominal viscera. The nine regions thus formed are: epigastrium; right and left hypochondrium; central or umbilical; right and left lumbar; hypogastrium or suprapubic; right and left iliac fossa.
ANTERIOR ABDOMINAL WALL

Skeletal landmarks

The superior boundary of the anterior abdominal wall is formed by several clear landmarks (Fig. 60.11). In the midline superiorly lies the xiphoid process. From this point, the costal margins extend to either side from the seventh costal cartilage at the xiphisternal joint to the tip of the twelfth rib (the latter is often difficult to feel in the obese or if it is short). The lowest part of the costal margin lies in the midaxillary line and is formed by the inferior margin of the tenth costal cartilage. The tip of the lower border of the ninth costal cartilage can usually be defined as a distinct 'step' along the costal margin.
The inferior boundary of the anterior abdominal wall is formed, in order, by the iliac crest, which descends from the tubercle of the iliac crest to the anterior superior iliac spine; the inguinal ligament, which runs downwards and forwards to the pubic tubercle; and the pubic crest, which runs from the pubic tubercle laterally to the pubic symphysis in the midline. The pubic tubercle can be identified by direct palpation in thin individuals and can be detected, even in
the obese, by palpation of the tendon of adductor longus, which runs up to its attachment on the pubis directly below the pubic tubercle. The tendon is best felt in tension with the hip flexed, abducted and externally rotated.

The posterolateral boundary is defined by the midaxillary line.

**Soft tissue landmarks**

**Umbilicus**

The umbilicus is an obvious but very inconstant landmark. In the supine adult, it usually lies at the level of the disc between the third and fourth lumbar vertebrae. The bifurcation of the abdominal aorta then lies about 2 cm caudal to the umbilicus. In the erect position, in children and in the obese, or in individuals with a pendulous abdomen, the umbilicus may lie at a lower level.

**Rectus abdominis**

In a thin and muscular individual, the tendinous intersections of rectus abdominis may be visible when the muscle is tensed by lifting the head against resistance or by sitting up: the intersections are usually situated at the level of the umbilicus, the level of the xiphoid process and mid way between these two points.

**Linea alba**

The linea alba is usually only visible in thin muscular individuals. It is wide and obvious above the umbilicus, but is almost linear and invisible below this level.

**Linea semilunaris**

The linea semilunaris lies along the lateral margin of the rectus sheath and is visible as a shallow curved groove in muscular individuals when the abdominal muscles are tensed, e.g. by sitting up from the lying position.

**Inguinal region**

The two commonly described surface markings in the inguinal region are the mid-inguinal point and the midpoint of the inguinal ligament.

**Mid-inguinal point**

The mid-inguinal point lies at the midpoint of the line between the symphysis pubis and the anterior superior iliac spine. It is superior to the point of palpation of the pulse of the femoral artery as it emerges from beneath the inguinal ligament. The approximate surface marking of the deep inguinal ring lies immediately above the mid-inguinal point, and is a useful landmark for palpation of the origin of an indirect inguinal herniae sac.
Midpoint of the inguinal ligament

The midpoint of the inguinal ligament lies halfway between the pubic tubercle and the anterior superior iliac spine, and is directly lateral to the origin of the inferior epigastric vessels as they lie on the posterior wall of the inguinal canal.
INTRA-ABDOMINAL VISCERA

The surface markings of the intra-abdominal viscera are variable and depend on age, body habitus, nutritional state, phase of ventilation and body position. The use of radiological imaging of the abdominal viscera means that the location of viscera by surface markings is almost obsolete in modern clinical practice. The following descriptions are at best regarded as the most common or approximate markings in a healthy supine individual (Fig. 60.12).

Fig. 60.12  Intra-abdominal visceral landmarks. 1. Gallbladder. 2. Duodenum. 3. Appendix. 4. Root of small bowel mesentery.

(Photograph by permission from Lumley JSP 2002 Surface Anatomy. 3rd edn.)
Stomach

The stomach lies in a curve within the left hypochondrium and epigastrium although, when distended and pendulous, it may lie as far down as the central or hypogastric regions. The epigastrium is the usual place to auscultate for a 'succussion splash' caused by chronic gastric stasis in upper intestinal obstruction.

Duodenum

The first part of the duodenum sometimes lies just above the trans-pyloric plane, depending on its mobility and length. The second part usually lies in the transpyloric plane just to the right of the midline, and the third part usually lies in the subcostal plane across the midline. The fourth part often lies in the transpyloric plane to the left of the midline, although its position varies according to the length of its mesentery.

Small bowel and its mesentery

The small bowel is usually referred to as lying in the central umbilical region, but often occupies part of both iliac fossae, both lumbar regions and the hypogastrium. The small bowel mesentery runs obliquely in a line from a point 2 cm to the left of the body of the second lumbar vertebra above the subcostal plane, to a point just anterior to the right sacroiliac joint just below the interspinous plane.

Appendix

The appendix is highly variable both in its length and in its position. Its base is commonly referred to as lying beneath a point marked two-thirds of the way along a line joining the umbilicus to the anterior superior iliac spine.

Liver

The inferior border of the liver extends along a line that passes from the right 10th costal cartilage to the left fifth rib in the midclavicular line. The upper border of the liver follows a line that passes from the fifth rib in the midclavicular line on the right to the equivalent point on the left. This upper border curves slightly downwards at its centre and crosses the midline behind the xiphoid. The right border of the liver is curved to the right and joins the upper and lower right limits. The outline of the liver may be defined by the dull note it gives on percussion when compared with the resonance of the lungs above and the hollow abdominal viscera below.
The lower edge of a normal liver cannot usually be palpated, even in women and children, in whom the liver is at a slightly lower level. What is often mistaken for the liver in abdominal palpation is the bulge of rectus abdominis above its upper tendinous intersection.

Gallbladder

The fundus of the gallbladder is very variable in location. It is commonly identified with the tip of the ninth costal cartilage (in the transpyloric plane), near the junction of the linea semilunaris with the costal margin.

Spleen

The spleen lies beneath the ninth, 10th and 11th ribs on the left side. Its surface markings can be delineated on the lower posterior thoracic wall by defining its axis, which extends from a point 5 cm to the left of the midline at the level of the 10th thoracic spine, and passes laterally along the line of the tenth rib to the midaxillary line.
RETROPERITONEAL VISCERA

The surface projections of the retroperitoneal viscera are fairly reliable but have little clinical use since most interventions and procedures are guided by radiological imaging.

Pancreas

The surface projection of the head of the pancreas lies within the duodenal curve. The neck lies in the transpyloric plane, behind the pylorus in the midline. The body passes obliquely up and to the left for approximately 10 cm, its left part lying a little above the transpyloric plane. The tail lies a little above and to the left of the intersection of the transpyloric and left lateral planes.

Kidney

The anterior and posterior surface projections of the kidneys are related to anterior and posterior abdominal wall landmarks. In the description that follows, all measurements are approximate. The right kidney lies 1.25 cm lower than the left. On the anterior surface, the centre of the hilum lies in the transpyloric plane 5 cm from the midline and slightly medial to the tip of the ninth costal cartilage. From the hilum, the outline of the anterior surface can be drawn 11 cm long and 4.5 cm broad, the upper pole being 2.5 cm, and the lower 7.5 cm, from the midline: since the transverse axis is oblique, the width thus shown is 1.5 cm less than the actual width of the kidney. On the posterior surface, the centre of the hilum lies opposite the lower border of the spinous process of the first lumbar vertebra and 5 cm from the midline. The outline of the posterior surface can be traced similarly to the anterior surface. The lower pole is 2.5 cm above the summit of the iliac crest. The kidneys are 2.5 cm lower in the standing than in the supine individual; they ascend and descend a little with respiration, which is of particular importance in endoscopic renal surgery. The lower pole of the normal right kidney may occasionally be felt in the thin individual, especially the female, by bimanual palpation on full inspiration.

Ureter

The ureter starts on either side approximately at the transpyloric plane (the left higher than the right), approximately 5 cm from the midline. Each passes downwards and somewhat medially to enter the bladder at a point marked superficially by the position of the pubic tubercle.

Abdominal aorta

The abdominal aorta starts just to the left of the midline, at the level of the
body of the 12th thoracic vertebra. It continues downwards for 10 cm as a band 2 cm wide, and bifurcates at the level of the fourth lumbar vertebra (which is marked by the transtubercular plane), 1.5 cm below and to the left of the umbilicus. The pulsations of the aorta can be felt in a thin individual in the supine position by pressing firmly in the midline backwards onto the vertebral column. An easily palpable aorta in an obese person should raise the suspicion of an aneurysm, to be checked by radiological imaging.

**Visceral arteries**

The coeliac trunk arises from the aorta immediately after it enters the abdomen at the level of the 12th thoracic vertebra. The origin of the superior mesenteric artery usually lies above the transpyloric plane, and that of the inferior mesenteric artery lies at the level of the body of the third lumbar vertebra, in the subcostal plane.

**Renal arteries**

The renal arteries can be projected as broad lines running laterally for 4 cm from the aorta just inferior to the transpyloric plane; the left inclines across the plane.

**Iliac arteries**

The surface projection of the common iliac artery corresponds to the superior one-third of a broad line, which is laterally slightly convex, from the aortic bifurcation to a point mid-way between the anterior superior iliac spine and the pubic symphysis. The external iliac artery corresponds to the inferior two-thirds of this line.

**Superior gluteal artery**

The surface marking of the exit of the superior gluteal artery from the pelvis corresponds to the junction of the upper and middle thirds of a line joining the posterior superior iliac spine to the apex of the greater trochanter.

**Inferior gluteal artery**

The surface marking of the exit of the inferior gluteal artery from the pelvis lies near the midpoint of a line joining the posterior superior iliac spine and the ischial tuberosity.

**Inferior vena cava**

The inferior vena cava starts at the level of the body of the fifth lumbar vertebra, usually in the transtubercular plane (2.5 cm below the supracristal plane). From this level it can be represented by a band, running vertically and
2.5 cm to the right of the midline. The inferior vena cava leaves the abdomen by traversing the diaphragm at the level of the eighth thoracic vertebra, directly behind the sternal extremity of the right sixth costal cartilage.
CLINICAL PROCEDURES

Pneumoperitoneum for laparoscopy

The establishment of a pneumoperitoneum is frequently performed by accessing the peritoneal cavity at the level of the umbilicus. Most commonly done just below the umbilicus, the incision through the linea alba allows access to the peritoneum at a point where there is relatively little extraperitoneal fat present and where the linea alba is relatively wide.

Surgical incisions

Most surgical incisions are performed according to surgical imperatives rather than anatomical constraints. The paramedian incision has been used to decrease the risk of incisional hernia. The skin and anterior fascial incision is made over the belly of rectus abdominis, at the level required. The muscle is displaced laterally, in order not to interfere with its neurovascular supply (which enters laterally), and the posterior rectus sheath is then incised in the paramedian plane. This approach allows rectus abdominis to lie between the two fascial incisions once the wound is closed.

Intestinal stomas (ileostomy, colostomy, caecostomy)

Where possible, intestinal stomas are usually formed through trans-rectus incisions. A cruciate incision is made in the anterior rectus sheath and the muscle fibres parted until the posterior sheath is reached. The latter is then incised without injury to the epigastric vessels (inferior or superior, depending on the level). This incision offers the advantage that fibres of rectus abdominis act to support the stoma: they provide a dynamic, contractile surround that tends to reduce the risk of herniation occurring around the stoma.

Suprapubic catheterization

The urinary bladder is commonly accessed for short- or long-term catheterization through the anterior abdominal wall. As the bladder fills, the upper part of its dome comes to lie in the preperitoneal space in the suprapubic region, and it can be relatively easily accessed via transcutaneous puncture in the midline (because there are no major neurovascular structures at this level and the linea alba is relatively thin).
REFERENCES

CHAPTER 61 – Anterior abdominal wall

The anterior abdominal wall extends from the costal margins and xiphoid process superiorly to the iliac crests, pubis and pubic symphysis inferiorly. It overlaps and is connected to both the posterior abdominal wall and paravertebral tissues. It forms a continuous but flexible sheet of tissue across the anterior and lateral aspects of the abdomen. The anterior abdominal wall is composed of the integument, muscles and connective tissue lining the peritoneal cavity (Figs 61.1–61.5). It has an important role in maintaining the form of the abdomen and is involved in many physiological activities. Anterior abdominal wall tissues form the inguinal canal that connects the abdominal cavity to the scrotum in men or labia majora in women, and also form the umbilicus; both of these sites are of considerable clinical importance.

Fig. 61.1 The left anterolateral abdominal wall muscles.
Fig. 61.2 Muscles of the left side of the trunk. External oblique has been removed to show internal oblique, but its digitations from the ribs have been preserved. The sheath of rectus abdominis has been opened and its anterior lamina removed.
Fig. 61.3  The cutaneous branches of the lower intercostal and lumbar nerves. Portions of the muscles of the anterior abdominal wall have been removed, including most of the anterior layer of the rectus sheath and parts of rectus abdominis.
Fig. 61.4  Deep muscles and arterial supply of the anterolateral abdominal wall. The greater part of the left rectus abdominis has been removed to show the superior and inferior epigastric vessels.
SKIN AND SOFT TISSUE

The integument of the anterior abdominal wall comprises skin, soft tissues, lymphatic and vascular structures, and segmental nerves. The outer layer is formed from the skin and subcutaneous fat. The skin is non-specialized and variably hirsute, depending on the sex and race. All post-pubertal individuals have some extension of the pubic hair onto the anterior abdominal wall skin, although this is commonly most pronounced in males, in whom the hair may extend almost up to the umbilicus in a triangular pattern. The subcutaneous fat of the abdominal wall is highly variable in thickness and is one of the areas where excess fat is stored during periods of obesity, particularly in males.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The anterior abdominal wall receives its blood supply from paired superior and inferior epigastric arteries running vertically through the tissues, and from paired posterior intercostal, subcostal and lumbar vessels running obliquely around the anterolateral aspects of the abdomen.

**Superior epigastric artery and veins**

The superior epigastric artery is a terminal branch of the internal thoracic artery. It descends between the costal and xiphoid slips of the diaphragm, accompanied by two or more veins (Fig. 61.4). The vessels pass anterior to the lower fibres of transversus thoracis and the upper fibres of transversus abdominis. The artery enters the rectus sheath behind rectus abdominis and runs down to anastomose with the inferior epigastric artery usually above the level of the umbilicus. Branches supply rectus abdominis and perforate the sheath to supply the abdominal skin. A branch given off in the upper rectus sheath passes anterior to the xiphoid process of the sternum and anastomoses with the same contralateral branch. This vessel may give rise to troublesome bleeding during surgical incisions that extend up to and alongside the xiphoid process. The superior epigastric artery supplies small branches to the anterior part of the diaphragm. On the right, small branches reach the falciform ligament, where they anastomose with branches arising from the hepatic artery.

**Inferior epigastric artery and veins**

The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament (Fig. 61.6). Its accompanying veins, usually two, drain into the external iliac vein. It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring. It lies posterior to the spermatic cord, but is separated from it by the transversalis fascia. It pierces the transversalis fascia which forms the flimsy posterior support of rectus abdominis, and ascends between the muscle and the fascia and overlying pre-peritoneal connective tissue. In this part of its course, it raises the parietal peritoneum of the anterior abdominal wall as the lateral umbilical fold but has little supporting tissue posteriorly. Disruption of the artery, by surgical incisions e.g. for laparoscopic ports or drains, is not uncommon and the resulting haematoma may expand to considerable size because of the lack of tissue against which the bleeding is effectively compressed. The artery divides into numerous branches. Those which anastomose with branches of the superior epigastric artery do so posterior to rectus abdominis at a variable height above the umbilicus. The inferior epigastric vessels are usually significantly larger than the superior vessels and provide the ‘dominant’ supply to rectus abdominis. Preparatory ligation of the inferior epigastric artery is often performed for myo(cutaneous) flaps using the mid or lower rectus abdominis based on the superior epigastric artery to allow expansion of the superior arterial flow to improve viability of the flap. Branches anastomose with terminal branches of the lower six posterior intercostal arteries posterior to rectus abdominis at the lateral border close to the sheath. The artery is an important inferomedial relation of the deep inguinal ring, and may be damaged during extensive medial dissection of the deep ring during hernia repair, particularly when this is performed in the preperitoneal plane. The vas deferens in the male, or round ligament in the female, wind laterally round it. It has the following branches: the cremasteric artery, a pubic branch, and muscular and cutaneous
The cremasteric artery accompanies the spermatic cord in males and supplies the cremaster and other coverings of the cord. It anastomoses with the testicular artery. In females it is small and accompanies the round ligament. A pubic branch, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator artery. Occasionally, the pubic branch of the inferior epigastric artery is larger than the main obturator artery origin, and it supplies the majority of flow into the obturator artery in the thigh. It is then referred to as the aberrant obturator artery. It lies close to the medial border of the femoral ring and may be damaged in medial dissection of the ring during femoral hernia repair. Muscular branches supply the abdominal muscles and peritoneum, and anastomose with the circumflex iliac and lumbar arteries. Cutaneous branches perforate the aponeurosis of external oblique, supply the skin and anastomose with branches of the superficial epigastric artery.

Sometimes the inferior epigastric artery arises from the femoral artery. It then ascends anterior to the femoral vein into the abdomen to follow its course as above. It occasionally arises from the external iliac artery, in common with an aberrant obturator artery and, rarely, from the obturator artery.

The superior and inferior epigastric arteries are important sources for a potential collateral circulation between the internal thoracic artery and the external iliac artery in situations where flow in the thoracic or abdominal aorta is compromised. Small tributaries of the inferior epigastric vein drain the skin around the umbilicus and anastomose with the terminal branches of the umbilical vein, draining the inner surface of the umbilicus via the falciform ligament. These anastomoses may open widely in cases of portal hypertension, when portal venous blood may drain into the systemic circulation via the inferior epigastric vessels. The radiating dilated veins seen
under the umbilical skin are referred to as the 'caput medusae'.

**Posterior intercostal, subcostal and lumbar arteries**

The 10th and 11th posterior intercostal arteries and the subcostal artery emerge from under the subcostal groove of their respective ribs and pass into the tissues of the anterior abdominal wall. They run through the aponeurosis of transversus abdominis and lie deep to the fibres of internal oblique. The lumbar arteries also cross the aponeurosis of transversus abdominis and lie deep to internal oblique. The arteries on either side run forward, giving off muscular branches to the overlying internal and external oblique, before anastomosing with the lateral branches of the superior and inferior epigastric arteries at the lateral border of the rectus sheath (Fig. 61.7). Perforating cutaneous vessels run vertically through the muscles to supply the overlying skin and subcutaneous tissue. A small contribution to the supply of the lower abdominal muscles comes from branches of the deep circumflex iliac arteries.

*Fig. 61.7* Arrangement of the anterolateral abdominal wall vessels at the level of the mid abdomen.
Lymphatic drainage
The lymphatic vessels of the anterior abdominal wall lie both superficial and deep to the deep fascia.

**Superficial vessels**
The superficial lymphatic vessels accompany the subcutaneous blood vessels. Vessels from the lumbar and gluteal regions run with the superficial circumflex iliac vessels. Those from the infra-umbilical skin run with the superficial epigastric vessels. Both drain into the superficial inguinal nodes. The supra-umbilical region is drained by vessels running obliquely up to the pectoral and subscapular axillary nodes, and there is some drainage to the parasternal nodes.

**Deep vessels**
The deep lymphatic vessels accompany the deep arteries. The vessels from the posterior portion of the abdominal wall pass with the lumbar arteries to drain into the lateral aortic and retro-aortic nodes. Vessels from the upper anterior abdominal wall run with the superior epigastric vessels to the parasternal nodes. Vessels of the lower abdominal wall drain into the circumflex iliac, inferior epigastric and external iliac nodes.
SEGMENTAL NERVES

The seventh to the 12th lower thoracic ventral rami continue anteriorly from the intercostal spaces into the abdominal wall (Fig. 61.3). Approaching the anterior ends of their respective spaces, the seventh and eighth nerves curve superomedially across the deep surface of the costal cartilages between the digitations of transverse abdominis. They reach the deep aspect of the posterior layer of the aponeurosis of internal oblique. Both the seventh and eighth nerves then run through this aponeurosis, pass posterior to rectus abdominis and supply branches to the upper portion of the muscle. They pass through the muscle near its lateral edge and pierce the anterior rectus sheath to supply the skin of the epigastrium.

The ninth to 11th intercostal nerves pass from their intercostal spaces between digitations of the diaphragm and transversus abdominis. They enter the layer between transversus abdominis and internal oblique. Here, the ninth nerve runs forwards almost horizontally, whereas the tenth and 11th pass inferomedially. At the lateral edge of rectus abdominis, the nerves pierce the posterior layer of the aponeurosis of internal oblique and pass behind the muscle to end, like the seventh and eighth intercostal nerves, with cutaneous branches. The ninth nerve supplies skin above the umbilicus, the tenth supplies skin, which includes the umbilicus, and the 11th supplies skin below the umbilicus (see Fig. 15.12 and Chapters 42, 45 and 79). The 12th thoracic nerve (subcostal nerve) connects with the first lumbar ventral ramus (dorsolumbar nerve). It accompanies the subcostal vessels along the inferior border of the 12th rib, passing behind the lateral arcuate ligament and kidney and anterior to the upper part of the quadratus lumborum. It perforates the transversus abdominis fascia, running deep to the internal oblique, to be distributed like the lower intercostal nerves. It supplies the anterior gluteal skin reaching down to the greater trochanter.

The seventh to 12th intercostal nerves supply the intercostal, subcostal and abdominal muscles. The tenth, 11th and 12th supply serratus posterior inferior. All six nerves also provide sensory fibres to the costal parts of the diaphragm and related parietal pleura and peritoneum. Like the upper intercostal nerves, they give off collateral and lateral cutaneous branches before they reach the costal angles. The collateral branch may rejoin its parent nerve but, if it does, it leaves it again near the lateral border of rectus abdominis. It then runs forward, through the muscle and its anterior sheath near the linea alba to supply the overlying skin. The lateral cutaneous branches pierce the intercostal muscles and external oblique and divide into anterior and posterior branches. These branches supply the skin of the abdomen and back. The anterior branches supply external oblique. The posterior branches pass back to supply the skin over latissimus dorsi. Each lateral cutaneous nerve descends as it pierces external oblique and the
superficial fascia and reaches the skin on a level with the anterior and posterior cutaneous nerves of the segment.

**Dermatomes**

The dermatomes of the anterior abdominal wall are shown in Figure 15.12.
SOFT TISSUE

Superficial fascia

The superficial fascia of the abdominal wall consists mostly of a single layer that contains a variable amount of fat. It lies between the skin and muscles of the anterior abdominal wall. In the lower part, the fascia differentiates into superficial and deep layers between which lie superficial vessels and nerves and, in the region of the groin, superficial inguinal lymph nodes.

Superficial layer

Where present, the superficial layer is thick, areolar in texture and contains a variable amount of fat. It is often greatly thickened in obese individuals. Inferiorly, it lies superficial to the inguinal ligament and is continuous with the superficial fascia of the thigh. In the male, this layer continues over the penis and outer surface of the spermatic cord into the scrotum, where it changes its character. In this region it is generally thin, with very little adipose tissue present and is pale red in colour. In the scrotum it also contains smooth muscle fibres, which form the dartos muscle. From the scrotum it may be traced backwards into continuity with the superficial fascia of the perineum. In the female, it continues from the suprapubic skin of the abdomen into the labia majora and perineum.

Deep (membranous) layer

When present as a distinct entity, the deep layer of the fascia is more membranous than the superficial, and contains elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of external oblique, but in the midline it is intimately adherent to the linea alba and symphysis pubis. In the male, it extends onto the dorsum of the penis and forms part of the superficial ligament of the penis. Superiorly, it is continuous with the superficial fascia over the remainder of the trunk. Inferiorly, it lies superficial to the inguinal ligament and fuses with the overlying superficial layer and the underlying fascia lata in the inguinal flexure line or skin crease of the thigh.

In the male, the deep layer of the fascia continues inferiorly and medially over the penis and spermatic cord to the scrotum, where it becomes continuous with the membranous layer of the superficial fascia of the perineum. In the female, it continues into the labia majora and is continuous with the fascia of the perineum.

In the child, the testis can frequently be retracted out of the scrotum into the loose areolar tissue between external oblique and the deep layer of superficial fascia over the inguinal canal. This ‘space’ is sometimes called the superficial inguinal pouch.
**Transversalis fascia**

The transversalis fascia is a thin layer of connective tissue lying between the inner surface of transversus abdominis and the extraperitoneal fat. It is part of the general layer of fascia between the peritoneum and the abdominal wall. Posteriorly, it is continuous with the anterior layer of the thoracolumbar fascia, and it forms a continuous sheet anteriorly. Inferiorly, it is continuous with the iliac and pelvic fasciae, and superiorly it blends with the fascial covering of the inferior surface of the diaphragm. It is attached to the entire length of the iliac crest between the origins of transversus abdominis and iliacus and to the posterior margin of the inguinal ligament between the anterior superior iliac spine and the femoral vessels. In the inguinal region it is thick and dense, and augmented by the aponeurosis of transversus abdominis. Medial to the femoral vessels it is thin and fused to the pubis behind the conjoint tendon. Anterior to the femoral vessels, fascia extends down from the fascia transversalis to form the anterior part of the femoral sheath. The fascia is strengthened here by fibres, which arch transversely. Some fibres spread laterally towards the anterior superior iliac spine, some fibres run medially behind rectus abdominis, and some descend to the pubis behind the conjoint tendon. These arched fibres constitute the deep crural arch. The curved fibres of the deep crural arch thicken the inferomedial part of the rim of the deep inguinal ring. The spermatic cord in the male, or the round ligament of the uterus in the female, pass through the transversalis fascia at the deep inguinal ring. This opening is not visible during dissection through the skin because the transversalis fascia is prolonged on these structures as the internal spermatic fascia, but it can be seen from within the abdomen once the peritoneum has been stripped off. The internal spermatic fascia surrounds the testis and blends with the areolar tissue on the parietal layer of the tunica vaginalis: it may contain smooth muscle fibres.

**Extraperitoneal connective tissue**

The extraperitoneal connective tissue is a layer of areolar tissue lying between the peritoneum and the fasciae lining the abdominal and pelvic cavities. The amount of extraperitoneal tissue varies: it is especially abundant on the posterior wall of the abdomen, particularly around the kidneys, where it contains much adipose tissue; variable in thickness on the anterolateral wall, where it is thin in children and normal adults but often thickened in the obese, particularly in males; scanty in the suprapubic region, above the iliac crest and in the pelvis. Extraperitoneal tissue is continuous with the epimysium of the muscles of the abdominal wall.
MUSCLES

ANTEROLATERAL MUSCLES OF THE ABDOMEN

Rectus abdominis, pyramidalis, external oblique, internal oblique and transversus abdominis constitute the anterolateral muscles of the abdomen. They act together to perform a range of functions, some of which involve the generation of a positive pressure within one or more body cavities. Although many of these activities may occur with no ‘forced assistance’, activities such as expiration, defecation and micturition may be aided by the generation of a positive intra-abdominal pressure. Parturition, coughing and vomiting always require such a positive pressure. Under resting conditions, the tone developed within the muscles provides support for the abdominal viscera and retains the normal contour of the abdomen. The consequences of lack of muscular support can be seen in conditions such as ‘prune belly syndrome’, where there is congenital absence of these muscles.

Active contraction of the muscles provides an important role in the maintenance of abdominal wall tone when the intra-abdominal pressure is increased. The compression of the abdominal cavity required to increase the internal pressure is brought about mainly by the contraction of the diaphragm. The bony pelvis and lower thoracic cage provide an almost incompressible structure to part of the abdominal wall. During the generation of positive intra-abdominal pressure, the abdominal wall acts to hold the position of the wall fixed, rather than to generate pressure directly: because the majority of the abdominal wall is muscular, the anterolateral abdominal wall muscles must be synchronously contracted to prevent displacement of the viscera and the resultant loss of pressure. The oblique muscles, acting through the anterior aponeurosis and the rectus sheath, provide the majority of this tension, although transversus abdominis and rectus abdominis also contribute.

The lateral muscles, external oblique, internal oblique and transversus abdominis, have the greatest roles in these functions, tensing the rectus sheath and linea alba. The anterolateral abdominal muscles contribute little to the movements of the trunk during normal sitting and standing, which are movements controlled predominantly by the paravertebral and spinal muscles. However, movements of the trunk against resistance or when the individual is supine require the anterolateral abdominal muscles. Rectus abdominis is the most important in these situations, causing anterior flexion of the trunk. If the pelvic girdle is fixed, flexion of the thorax and pectoral girdle occurs. With a fixed thoracic cage, contraction of rectus abdominis causes the pelvis to lift and tilt to lie more nearly in a horizontal plane. Lateral flexion and rotation of the trunk against resistance is provided by unilateral contraction of the oblique muscles.

Rectus abdominis

Rectus abdominis is a long, strap-like muscle that extends along the entire length of the anterior abdominal wall. It is widest in the upper abdomen and lies just to the side of the midline. The paired recti are separated in the midline by the linea alba (Fig. 61.4).

The muscle fibres of rectus abdominis are interrupted by three fibrous bands or tendinous intersections. One is usually situated at the level of the umbilicus, another opposite the free end of the xiphoid process and a third about midway between the
other two. These intersections pass transversely or obliquely across the muscle in a zigzag manner. They are rarely full-thickness and may extend only half-way through the body of the muscle. They usually fuse with the fibres of the anterior lamina of the sheath of the muscle. Sometimes, one or two incomplete intersections are present below the umbilicus. The intersections may occur during development or may represent the myosepta delineating the myotomes that form the muscle.

The medial border of rectus abdominis is closely related to the linea alba. Its lateral border may be visible on the surface of the anterior abdominal wall as a curved groove, the linea semilunaris, which extends from the tip of the ninth costal cartilage to the pubic tubercle. In a muscular individual it is readily visible, even when the muscle is not actively contracting, but in many normal and obese individuals it may be completely obscured.

Attachments

Rectus abdominis arises by two tendons. The larger, lateral tendon is attached to the crest of the pubis and may extend beyond the pubic tubercle to the pectineal line. The medial tendon interlaces with the contralateral muscle and blends with the ligamentous fibres covering the front of the symphysis pubis. Additional fibres may arise from the lower part of the linea alba. Superiorly, rectus abdominis is attached by three slips of muscle to the fifth, sixth and seventh costal cartilages. The most lateral fibres are usually attached to the anterior end of the fifth rib. Sometimes this slip is absent, and occasionally it may extend to the fourth and third ribs. The most medial fibres are occasionally connected to the costoxiphoid ligaments and the side of the xiphoid process. In males, the pubic attachment of rectus abdominis may run over the anterior surface of the symphysis pubis and become continuous with the attachment of the gracilis and the fascia lata to the pubis.

Vascular supply

Rectus abdominis is supplied principally by the superior and inferior epigastric arteries. The inferior epigastric artery tends to be larger in calibre than the superior. Small terminal branches from the lower three posterior intercostal arteries, the subcostal artery, the posterior lumbar arteries and the deep circumflex artery may provide some contribution, particularly to the lateral edges and the lower attachments, and they form small anastomoses with the lateral branches of the epigastric arteries. Rectus abdominis provides an excellent myocutaneous flap, either pedicled or free, because of the excellent vascularity provided by the epigastric vessels and because the muscle belly is separated from surrounding tissue within the rectus sheath. The upper half of the muscle may be used for breast reconstruction or augmentation of tissue loss on the anterior thorax. The lower half may be used in the region of the thigh and may be rotated on its lower attachments, passed through the pelvis and delivered into the perineum for reconstruction after radical pelvic and perineal resections.

Innervation

Rectus abdominis is innervated by the terminal branches of the ventral rami of the lower six or seven thoracic spinal nerves via the lower intercostal and subcostal nerves.
Actions

The recti contribute to the flexion of the trunk. They also contribute to the maintenance of abdominal wall tone required during straining.

Rectus sheath

Rectus abdominis on each side is enclosed by a fibrous sheath. The anterior portion of this sheath extends the entire length of the muscle and fuses with the periosteum of the muscle attachments. Posteriorly, the sheath is complete in the upper two-thirds of the muscle. In the lower one-third, the posterior layer of the sheath stops approximately midway between the umbilicus and the pubis. In most individuals this is a clearly defined line, although the transition may not always be clear-cut in others. The lower border of the posterior sheath is called the arcuate line. Below this level, rectus abdominis is enclosed posteriorly by the transversalis fascia and extraperitoneal connective tissue (Figs 61.8 and 61.9). The rectus sheath is formed from decussating fibres from all three lateral abdominal muscles. External oblique, internal oblique and transversus abdominis each forms a bilaminar aponeurosis at their medial borders. The fibres from all three anterior leaves run obliquely upwards, whereas the posterior leaves run obliquely downwards at right angles to the anterior leaves.

**Fig. 61.8** Transverse sections through the anterior abdominal wall: A, immediately above the umbilicus; B, below the arcuate line. The bilaminar nature of each muscular aponeurosis is difficult to illustrate in cross-section. The fibres appear to fuse into a single sheet during formation of the rectus sheath. Note that rectus is supported directly by the transversalis fascia below the arcuate line.
Fig. 61.9 Rectus sheath. Computed tomography scan (A) and diagram (B) of the anterior abdominal wall, demonstrating the formation of the rectus sheath above the umbilicus. The anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique, fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis of transversus abdominis.

The anterior rectus sheath is composed of both leaves of the aponeurosis of external oblique and the anterior leaf of the aponeurosis of internal oblique fused together. The posterior rectus sheath is composed of the posterior leaf of the aponeurosis of internal oblique and both leaves of the aponeurosis transversus abdominis (Fig. 61.10). Because of this arrangement, both the anterior and posterior layers of the rectus sheath consist of three layers of fibres with the middle layer running obliquely at right angles to the other two. At the midline, the anterior and posterior layers are closely approximated. Fibres of each layer decussate to the opposite side of the sheath, forming a continuous aponeurosis with the contralateral muscles (Fig. 61.11). Fibres also decussate anteroposteriorly, crossing from anterior sheath to posterior sheath.
The dense fibrous line caused by this decussation is called the linea alba. The external oblique, internal oblique and transversus abdominis muscles can thus be regarded as paired, digastric muscles with a central tendon in the form of the linea alba. These decussating fibres maybe used to identify the midline during surgical incisions, since they can be seen as oblique fibres crossing at right angles. Below the level of the arcuate line, the fibres forming the posterior rectus sheath rapidly cease running behind the rectus and all leaves pass into the anterior rectus sheath.

![Fig. 61.10 Rectus sheath. Computed tomography scan (A) and diagram (B) of the anterior abdominal wall, demonstrating the formation of the rectus sheath below the umbilicus. The posterior rectus sheath is formed by the transversalis fascia and extraperitoneal connective tissue.](image-url)
The concept of bilaminar aponeuroses of the external oblique muscles. Note that the fibres of the superficial and deep layers are approximately at right angles; decussations occur as part of the linea alba.

**Linea alba**

The linea alba is a tendinous raphe extending from the xiphoid process to the symphysis pubis and pubic crest. It lies between the two recti and is formed by the interlacing and decussating aponeurotic fibres of external oblique, internal oblique and transversus abdominis. It is visible only in the lean and muscular, as a slight groove in the anterior abdominal wall. A fibrous cicatrix, the umbilicus, lies a little below the midpoint of the linea alba, and is covered by an adherent area of skin. Below the umbilicus, the linea alba narrows progressively as the rectus muscles lie closer together. Above the umbilicus, the rectus muscles diverge from one another and the linea alba is correspondingly broader. The linea alba has two attachments at its lower end: its superficial fibres are attached to the symphysis pubis, and its deeper fibres form a triangular lamella that is attached behind rectus abdominis to the posterior surface of the pubic crest on each side. This posterior attachment of linea alba is named the ‘adminiculum lineae albae’. The linea alba is crossed from side to side by a few minute vessels.

In the fetus, the umbilicus transmits the umbilical vessels, urachus and, up to the third month, the vitelline or yolk stalk. It closes a few days after birth, but the vestiges of the vessels and urachus remain attached to its deep surface. The remnant of the fetal left umbilical vein forms the round ligamentum of the liver. The obliterated umbilical arteries form the medial umbilical ligaments, enclosed in peritoneal folds of the same name. The partially obliterated remains of the urachus persist as the median umbilical ligament.
Divarication of the recti

Thinning and widening of the upper linea alba may occur, most commonly as a result of obesity or chronic straining. This process disrupts the arrangement of the fibres of the bilaminar aponeurosis. Contraction of the anterolateral abdominal muscles fails to be transmitted across the midline through the linea alba and increased intra-abdominal pressure causes the abdominal viscera to protrude beneath the thinned tissue as a broad midline bulge. The recti become widely separated or divaricated. This is not true herniation, as all the layers of the abdominal wall in that region are intact.

Umbilical hernia

There are three varieties of umbilical hernia. In true congenital herniation, a defect is present from birth. This is usually simply the result of failure of closure of the umbilicus after retraction of the umbilical gut loop. Less commonly, the gut loop does not retract and remains, in part, outside the abdominal cavity. An infantile umbilical hernia is caused by stretching of the umbilical scar tissue, associated with increased intra-abdominal pressure. An acquired umbilical or paraumbilical hernia actually occurs through small areas of weakness in the linea alba, above or below the umbilical scar.

Pyramidalis

Attachments

Pyramidalis is a triangular muscle that lies in front of the lower part of rectus abdominis within the rectus sheath. It is attached by tendinous fibres to the front of the pubis and to the ligamentous fibres in front of the symphysis. The muscle diminishes in size as it runs upwards, and ends in a pointed apex that is attached medially to the linea alba. This attachment usually lies midway between the umbilicus and pubis, but may occur higher. The muscle varies considerably in size. It may be larger on one side than on the other, absent on one or both sides, or even doubled.

Vascular supply

Pyramidalis is supplied by branches of the inferior epigastric artery, with some contribution from the deep circumflex iliac artery. A small artery frequently crosses the midline posterior to the belly of the muscle to anastomose with the contralateral vessel. This may cause troublesome bleeding during surgical incisions that run down as far as the lower rectus sheath above the symphysis pubis.

Innervation

Pyramidalis is supplied by the terminal branches of the subcostal nerve, which is the ventral ramus of the 12th thoracic spinal nerve.

Actions

Pyramidalis contributes to tensing the lower linea alba, but is of doubtful physiological significance.

External oblique
Attachments

External oblique is the largest and the most superficial of the three lateral abdominal muscles (Fig. 61.1). It curves around the lateral and anterior parts of the abdomen and is attached to the external surfaces and inferior borders of the lower eight ribs. The attachments rapidly become muscular and interdigitate with the lower attachment of serratus anterior and latissimus dorsi along an oblique line that extends downwards and backwards. The upper attachments are close to the cartilages of the corresponding ribs, the middle ones arise from the ribs at some distance from their cartilages and the lowest are close to the apex of the cartilage of the 12th rib. The fibres of external oblique diverge as they pass to their lower attachments. Those from the lower two ribs pass nearly vertically downwards and are attached to the anterior half or more of the outer lip of the anterior segment of the iliac crest. The middle and upper fibres pass downwards and forwards and end in the anterior aponeurosis, along a line drawn vertically from the ninth costal cartilage to a little below the level of the umbilicus. The muscle fibres rarely descend beyond a line from the anterior superior iliac spine to the umbilicus. The posterior border of the muscle is free.

The inguinal ligament is formed by the margin of the aponeurosis of external oblique extending between the anterior superior iliac spine and the pubic tubercle. The deep fibres of the aponeurosis of external oblique are not initially parallel to the long axis of the inguinal ligament: they approach the ligament obliquely at an angle of 10–20°. On reaching the ligament, fibres turns medially, and most run along the ligament to reach the pubic tubercle. The deepest fibres of the aponeurosis spread out posteromedially to insert into the pectineal line.

The upper and lower rib attachments of the muscle may be absent. Digitions or even the entire muscle may be reduplicated. The upper attachments of the muscle are sometimes continuous with pectoralis major or serratus anterior.

Vascular supply

External oblique is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

Innervation

External oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves.

Actions

External oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure and lateral flexion of the trunk against resistance.

Inguinal ligament

The inguinal ligament is the thick, inrolled lower border of the aponeurosis of external oblique and stretches from the anterior superior iliac spine to the pubic tubercle. Its grooved abdominal surface forms the ‘floor’ of the inguinal canal. The ligament is not linear and has an inferior and an anterior convexity. At its lower border, it is
continuous with the fascia lata. The lateral half is rounded and lies more obliquely than the medial half. The latter gradually widens towards its attachment to the pubis, where it becomes more horizontal and supports the spermatic cord. At the medial end, some fibres do not attach to the pubic tubercle but extend in two directions. Some expand posteriorly and laterally to attach to the pectineal line, forming the lacunar ligament complex. Other fibres pass upwards and medially behind the superficial inguinal ring and external oblique to join the rectus sheath and the linea alba. These constitute the reflected part of the inguinal ligament. Fibres from either side decussate in the linea alba, similarly to the aponeurosis of the abdominal muscles.

**Internal oblique**

**Attachments**

Internal oblique lies deep to external oblique for the majority of its course (Fig. 61.2). It is thinner and less bulky than external oblique. Its fibres arise from the lateral two-thirds of the grooved upper surface of the inguinal ligament, where they form a common attachment with the iliac fascia to the inguinal ligament. Laterally, internal oblique is also attached to the anterior two-thirds of the intermediate line of the anterior segment of the iliac crest, and posteriorly some fibres are attached to the thoracolumbar fascia. The fibres originating from the posterior end of the iliac attachment pass upwards and laterally and are attached to the inferior borders and tips of the lower three or four ribs and their cartilages. Here, the attachments merge with those of the internal intercostals. The uppermost of these fibres form a short, free superior border. The fibres attached to the anterior iliac crest diverge and end in the anterior aponeurosis, which gradually broadens from below upwards. The uppermost part of the aponeurosis is attached to the cartilages of the seventh, eighth and ninth ribs. The fibres that originate from the inguinal ligament arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. They become tendinous, fuse with the corresponding part of the aponeurosis of transversus abdominis, and attach to the crest and medial part of the pectineal line, forming the conjoint tendon.

**Vascular supply**

Internal oblique is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

**Innervation**

Internal oblique is innervated by the terminal branches of the lower five intercostal nerves and the subcostal nerve from the ventral rami of the lower six thoracic spinal nerves, in addition to a small contribution from the iliohypogastric and ilioinguinal nerves from the ventral ramus of the first lumbar spinal nerve.

**Actions**

Internal oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and enables lateral flexion of the trunk against resistance.

**Cremaster**
Attachments

Cremaster consists of loosely arranged muscle fasciculi lying along the spermatic cord. It is variable in thickness and is thickest in young men. It may form an incomplete coating around the cord, known as the cremasteric fascia, which extends around the testis but lies within the external spermatic fascia. The attachment of the muscle arises mainly from the inferomedial border of internal oblique and transversus abdominis. A separate tendinous attachment may also occur to the middle of the inguinal ligament, extending as far as the anterior superior iliac spine. The medial portion is attached to the pubic tubercle and lateral pubic crest. The fibres spread out over the lateral aspect of the spermatic cord as it approaches the superficial inguinal ring. The shortest and most superior fasciculi turn inwards in front of the cord to join the medial part. The longer, lateral fasciculi blend with the fascia over the cord and upper part of the tunica vaginalis. In the female, a few fibres descending on the round ligament of the uterus represent the lateral part of cremaster. The medial part of the muscle is variably developed, and may be absent. It is attached to the pubic tubercle and the lateral pubic crest, the conjoint tendon and lower border of transversus abdominis. These fasciculi loop on the posteromedial aspect of the cord, interlacing with those of the lateral part. The entire muscle appears to form continuous loops that pass from the middle of the inguinal ligament as far as the tunica vaginalis, and then return to attach to the pubic tubercle.

Vascular supply

Cremaster is supplied by the cremasteric artery, a branch of the inferior epigastric artery.

Innervation

Cremaster is innervated by the genital branch of the genitofemoral nerve, derived from the first and second lumbar spinal nerves.

Actions

Cremaster pulls the testis up towards the superficial inguinal ring. Although its fibres are striated, it is not usually under voluntary control. Stroking the skin of the medial side of the thigh evokes a reflex contraction of the muscle, the cremasteric reflex, which is most pronounced in children. It may represent a protective reflex, and the cremaster may also have a role in testicular thermoregulation.

Transversus abdominis

Attachments

Transversus abdominis is the deepest of the lateral abdominal muscles (Fig. 61.5). It is attached to the lateral one-third of the inguinal ligament and the associated iliac fascia, the anterior two-thirds of the inner lip of the anterior segment of the iliac crest, the thoracolumbar fascia between the iliac crest and the 12th rib, and the internal aspects of the lower six costal cartilages. The costal attachments interdigitate with the attachment of the diaphragm. The muscle ends in an anterior aponeurosis. The lower fibres curve downwards and medially, together with those of the aponeurosis of internal oblique, and insert into the pubic crest and pectineal line to form the conjoint tendon. A band of fibres, sometimes muscular, may run from the lower border of the
muscle to the inguinal ligament and is called the inter-foveolar ligament. The remainder of the aponeurosis passes medially and the fibres decussate at, and blend with, the linea alba. The upper costal and anterior iliac fibres of transversus abdominis are short. The lower costal and posterior iliac fibres are longer, and the thoracolumbar fibres are longest. Near the xiphoid process, the aponeurosis is formed only 2–3 cm from the linea alba, so the muscular part of transversus abdominis extends behind rectus into the posterior layer of the rectus sheath. The medial edge of the muscle, at the start of the aponeurosis, curves first downwards and laterally, and is furthest from the lateral edge of the rectus sheath at the level of the umbilicus. It then curves downwards and medially towards the middle of the superior crus of the superficial inguinal ring.

Occasional defects filled with fascia may occur in the lower muscular and aponeurotic parts of both internal oblique and transversus abdominis. The two muscles are sometimes fused and, rarely, transversus abdominis may be absent.

Vascular supply

Transversus abdominis is supplied by branches from the lower posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex arteries and the posterior lumbar arteries.

Innervation

Transversus abdominis is innervated by the terminal branches of the lower five intercostal nerves, the subcostal nerve and the iliohypogastric and ilioinguinal nerves. These arise from the ventral rami of the lower six thoracic and first lumbar spinal nerves.

Actions

Transversus abdominis contributes mainly to the maintenance of abdominal tone and increasing intra-abdominal pressure.

Conjoint tendon

The conjoint tendon is formed from the lower fibres of internal oblique and the lower part of the aponeurosis of transversus abdominis. It is attached to the pubic crest and pectineal line. It descends behind the superficial inguinal ring and acts to strengthen the medial portion of the posterior wall of the inguinal canal. The attachment to the pectineal line is frequently absent. Medially, the upper fibres of the tendon fuse with the anterior wall of the rectus sheath, and laterally some fibres may blend with the interfoveolar ligament.

Inguinal canal

The inguinal canal is a natural hiatus in the tissues of the anterior abdominal wall, and is formed from the various layers of the wall in the region of the groin (Figs 61.12, 61.13, 61.14, 61.15, and see Fig. 76.2). Its size and form vary with age, and although it is present in both sexes it is most well developed in the male. The canal is an oblique tunnel, with deep and superficial openings or rings. It contains the spermatic cord in males, the round ligament of the uterus in females, and the ilioinguinal nerve in
both sexes.

Fig. 61.12 Superficial structures of the inguinal region and lower part of the anterior abdominal wall on the left side.
Fig. 61.13  Superficial structures of the inguinal region and lower part of the anterior abdominal wall on the left side: superficial aponeurotic layer removed.
Fig. 61.14 Dissection of the regions shown in Fig. 61.12, with part of external oblique removed.
The superficial inguinal ring is a hiatus in the aponeurosis of external oblique, just above and lateral to the crest of the pubis. The ring is actually triangular, and its apex points along the line of the deep fibres of the aponeurosis. Although it varies in size, it does not usually extend laterally beyond the medial one-third of the inguinal ligament—the ring is smaller in the female. The base lies along the crest of the pubis and its sides are the crura of the opening in the aponeurosis. The lateral crus is the stronger and is reinforced by fibres of the inguinal ligament inserted into the pubic tubercle. The medial crus is thin. The fibres attach to the front of the symphysis pubis and interlace with fibres from the opposite side. In the external layer of the investing fascia of external oblique, some fibres arch above the apex of the superficial inguinal ring as intercrural fibres. In the male, the lateral crus is curved to form a groove, in which the spermatic cord rests. Fibres from the aponeurosis of external oblique and overlying fascia continue downwards from the crura of the ring, and form a delicate tubular prolongation of fibrous tissue around the spermatic cord and testis. This is the external spermatic fascia and constitutes the outermost covering of the cord. The superficial inguinal ring is only a distinct aperture when the continuity of this fascia with the aponeurosis is interrupted.

Deep inguinal ring

The deep inguinal ring is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis approximately 1.25 cm above the inguinal ligament. It is oval, with an almost vertical long axis. Its size varies between individuals, and it is always much larger in the male. It is related above to the arched lower margin of transversus abdominis, and medially to the inferior epigastric vessels and the interfoveolar ligament, when that is present. Traction on the fascial ring exerted by internal oblique may constitute a valve-like safety mechanism when intra-abdominal pressure is increased.

Boundaries
The inguinal canal is a virtual space lying between the various layers formed from the lower tissues of the anterior abdominal wall. It lies obliquely and slants downwards and medially, parallel with and a little above the inguinal ligament. It extends from the deep to the superficial inguinal rings: the length depends on the age of the individual, but in the adult is between 3 and 5 cm long. The canal is bounded anteriorly by the skin, superficial fascia and aponeurosis of external oblique. In its lateral one-third, the anterior wall is reinforced by the muscular fibres of the internal oblique just above their origin from the inguinal ligament. Posteriorly lie the reflected inguinal ligament, the conjoint tendon and the transversalis fascia, which separate it from extraperitoneal connective tissue and peritoneum. Superiorly lie the arched fibres of internal oblique and transversus abdominis, forming the conjoint tendon, and inferiorly is the union of the transversalis fascia with the inguinal ligament and, at the medial end, the lacunar ligament.

In the newborn, the deep and superficial rings are nearly superimposed and the canal is extremely short. This creates an approximately oval defect in the abdominal wall. As the child grows, the anterior abdominal wall muscles grow rapidly, causing the positions of the rings to separate and the canal to lengthen. The defect thus becomes progressively more oblique until, in adulthood, the presence of separate anterior and posterior canal walls forms a ‘flap valve’ effect. Increases in intra-abdominal pressure transmitted through the posterior wall and the deep ring are supported by the presence of the thickest part of the overlying anterior wall. At the superficial ring and medial end of the anterior wall, where it is weakest, the posterior wall is strengthened by the conjoint tendon and the reflected inguinal ligament. The fibres of internal oblique and transversus abdominis, which form the conjoint tendon, are constantly active in standing; this activity increases during episodes of increased intra-abdominal pressure.

Relations

The inferior epigastric vessels are important posterior relations of the medial end of the canal (Fig. 61.16). They lie on the transversalis fascia as they ascend obliquely behind the conjoint tendon into the posterior portion of the rectus sheath.
Fig. 61.16 Deep structures of the inguinal canal. The aponeurosis of external oblique has been removed. For clarity, the fibres of internal oblique and rectus abdominis have been divided and the structures passing posteroinferiorly to the inguinal ligament have been excluded.

The inguinal triangle lies in the posterior wall of the canal. It is bounded inferiorly by the medial half of the inguinal ligament, medially by the lower lateral border of rectus abdominis and laterally by the inferior epigastric artery, and overlies the medial inguinal fossa and, in part, the supravesical fossa.

Lacunar ligament

The lacunar ligament is a thick triangular band of tissue lying mainly posterior to the medial end of the inguinal ligament. It measures approximately 2 cm from base to apex and is a little larger in the male. It is formed from fibres of the medial end of the inguinal ligament and fibres from the fascia lata of the thigh, which join the medial end of the inguinal ligament from below. The inguinal fibres run posteriorly and laterally to the medial end of the pectineal line and are continuous with the pectineal fascia. They form a near horizontal, triangular sheet with a curved lateral border which forms the medial border of the femoral canal. The apex of the triangle is attached to the pubic tubercle. A strong fibrous band, the pectineal ligament of Astley Cooper, extends laterally along the pectineal line from the pectineal attachment. The fibres from the fascia lata join the inferior/posterior border of the inguinal ligament; the latter, in combination with fibres from the transversalis fascia, fuses with the pectineal fascia as it joins the thickened periosteum of the pectineal line. This portion of the lacunar ligament forms the lower extension of the medial border of the femoral canal and femoral sheath.
HERNIAS OF THE ANTERIOR ABDOMINAL WALL

INGUINAL HERNIA

Although the inguinal canal is arranged such that the weaknesses in the anterior abdominal wall caused by the deep and superficial inguinal rings are supported, the region remains a potential cause of herniation. An inguinal hernia involves the protrusion of a viscus through the tissues of the inguinal region of the abdominal wall.

Indirect inguinal hernia

An indirect hernia is defined as arising lateral to the inferior epigastric vessels. Many indirect hernias are related to the congenital abnormal persistence of the vaginal process, others are acquired as a result of progressive weakening of the lateral and posterior walls of the canal. The hernia may pass through the deep ring or may expand the deep ring such that it is no longer a clear entity. Small indirect hernias tend to lie below and lateral to the fibres of the conjoint tendon, but larger hernias often distort and thin the tendon superiorly. Small hernias, which do not protrude beyond the inguinal canal, are covered by the same inner layers as the spermatic cord, including the internal spermatic fascia and cremaster. If the hernia extends through the superficial inguinal ring it is additionally covered by external spermatic fascia.

In hernias related to a persistent fully patent vaginal process, the hernia contents descend in front of the testis into the tunica vaginalis (complete congenital hernia) and the vaginal process and tunica form part of the hernial sac. Where the vaginal process is sealed off from the tunica vaginalis, the hernia contents descend to the top of the testis (incomplete congenital hernia). Although both types are related to a congenital abnormality, actual herniation into the potential sac may not occur until adult life, when it may happen as a consequence of increased intra-abdominal pressure or sudden muscular strain.

Direct inguinal hernia

A direct inguinal hernia is defined as arising medial to the inferior epigastric vessels. Direct hernias are always caused by an acquired weakness of the inguinal triangle in the medial posterior wall of the canal, and frequently extend through the anterior wall of the canal or superficial ring. The hernia may protrude through the transversalis fascia, between the conjoint tendon and the inferior epigastric vessels, and enter the inguinal canal. It may closely resemble an indirect hernia, in that the coverings are similar. Its clinical presentation can also mimic an indirect inguinal hernia. Other direct hernias arise either between the fibres of the conjoint tendon or by
eventration of the tendon such that it forms a thin covering to the hernia. In either case, a hernia enters the lower end of the canal, protruding through the superficial ring medial to the cord, and is covered by external spermatic fascia.

Clinical features of inguinal hernias

Indirect hernias often descend from lateral to medial in the same oblique angle as the canal, because of their origin in the lateral end of the inguinal canal. This is particularly true for congenital hernias. Direct hernias arise from the medial end of the canal and tend to protrude more directly anteriorly. With the patient in the supine position and the hernia reduced, pressure applied over the region of the deep inguinal ring may prevent appearance of an indirect hernia on standing or straining. This method of determining the type of hernia is fraught with difficulties. Indirect hernias may have a wide neck, and occlusion of the deep ring may not be possible with simple digital pressure. An acquired indirect hernia may arise medial to the deep ring. The angle of the descent of the hernia is also an unreliable guide, as it depends on the size of the defect in the posterior wall of the canal, the length of the canal and whether the hernia protrudes through the anterior wall. Direct hernias are more likely to have a wide-necked origin, making strangulation less likely.
FEMORAL HERNIA

A femoral hernia protrudes through the femoral ring. The femoral ring is normally closed by a femoral septum of modified extraperitoneal tissue, and is therefore a weak spot. In females, the ring is relatively large and subject to profound changes during pregnancy, which explains why femoral hernias are more common in women. When a section of intestine bulges through the ring, it pushes out a hernial sac of peritoneum. It is covered by extraperitoneal tissue (the femoral septum) and descends along the femoral canal to the saphenous opening. It is prevented from descending further along the femoral sheath by the narrow saphenous opening, by the vessels and by the close attachment of the superficial fascia and sheath to the lower part of the rim of the saphenous opening. The hernia hence turns forwards, distending the cribriform fascia and curving upwards over the inguinal ligament and the lower part of the aponeurosis of external oblique. While in the canal the hernia is usually small, because of the resistance of surrounding tissues, but it enlarges as it escape into the inguinal loose connective tissue. A femoral hernia first descends and then ascends forwards: pressure to reduce it should therefore be directed in the reverse order, with the thighs passively flexed for greatest relaxation.

The coverings of a femoral hernia are, from within outwards: the peritoneum, femoral septum, femoral sheath, cribriform fascia, superficial fascia and skin. A fibrous covering, the fascia propria, may lie outside the peritoneal sac and is frequently separated from it by adipose tissue. It represents a femoral septum which has been thickened to form a membranous sheet by hernial pressure. The fascia propria may easily be mistaken for the sac, and its contained extraperitoneal fat for omentum; the fat may resemble a lipoma, but dissection will reveal the true hernial sac in its centre. The intestine reaches only to the saphenous opening in incomplete femoral hernia, in contradistinction to complete hernia, in which it passes through the opening. The small size of an incomplete hernia renders it difficult to detect and therefore dangerous, especially in the corpulent. The site of strangulation varies: it may be at the neck of the hernial sac, more often it is at the junction of the falciform margin of the saphenous opening with the free edge of the pectineal part of the inguinal ligament, or it may be at the saphenous opening. The site of narrowing should be divided superomedially for a distance of 4–6 mm to avoid all normally positioned vessels and other important structures. Occasionally the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric artery descending almost vertically to the obturator foramen. This vessel sometimes curves along the edge of the lacunar part of the inguinal ligament, encircling the neck of a hernial sac, and may be inadvertently cut during enlargement of the femoral ring in reducing a femoral hernia.
The pubic tubercle is an important landmark in distinguishing inguinal from femoral hernias; the neck of the hernia is superomedial to it in inguinal hernia, but inferolateral in the femoral form.
LESIONS OF THE INTERCOSTAL NERVES

Lesions of individual intercostal nerves do not produce any appreciable clinical effects. The anterolateral muscles are innervated by a number of different nerves: injury to a single nerve will not reduce the tone of the muscle wall. The overlap between sequential dermatomes means that significant cutaneous anaesthesia is appreciated only after sectioning of at least two sequential nerves.
REFERENCES

The posterior abdominal wall consists of fasciae, muscles and their vessels and spinal nerves; the overlying skin is continuous with that of the back. It is not easily defined, and is best described as that part of the abdominal wall lying between the two mid-dorsal lines, below the posterior attachments of the diaphragm and above the pelvis. It is continuous laterally with the anterolateral abdominal wall, superiorly with the posterior wall of the thorax behind the attachments of the diaphragm and inferiorly with the structures of the pelvis. The spinal column forms part of its structure and the muscles and fasciae of the back are closely related to it, especially posterolaterally.

The major vessels and lymphatic channels, in addition to the peripheral autonomic nervous systems of the abdomen, pelvis and lower limbs lie on the posterior abdominal wall. These structures, together with several viscera (including the kidneys [Ch. 74], suprarenal glands [Ch. 72], pancreas [Ch. 70], ureters [Ch. 74] and parts of the gut tube [Chs 66 and 67]), lie beneath the posterior parietal peritoneum. These tissues and their surrounding connective and fascial planes are collectively referred to as the retroperitoneum.

It has been suggested that the retroperitoneum can be divided into several spaces according to their relationships to the fascial layers that surround the kidneys and ureters. In this description, the layers of the perirenal fascia enclose a perirenal space containing the kidney, suprarenal gland, upper ureter and their neurovascular supply. The anterior layer of the perirenal fascia is continuous across the midline anterior to the main neurovascular structures of the retroperitoneum, and the right and left perirenal spaces communicate, although this channel is limited and contains many of the midline neurovascular structures of the retroperitoneum. Behind the posterior layer of the perirenal fascia lies the posterior pararenal space. Anterior to the anterior layer of the perirenal fascia lies the anterior pararenal space, in which lie several retroperitoneal parts of the gut tube, including the duodenum and pancreas. The anterior pararenal spaces are also continuous across the midline and are limited posteriorly by the anterior communicating layer of the perirenal fascia and anteriorly by the parietal peritoneum. This description helps to explain why moderate amounts of fluid, blood or pus collecting in the retroperitoneum tend to remain constrained within the space in which they are formed although, for pathological processes such as tumour invasion, the fascial planes provide a weak barrier to local spread (Figs 62.1, 62.2).

Several structures, such as the pancreas, are referred to as being retroperitoneal. Although they are derived embryologically from the gut tube, they are not readily separated from the other retroperitoneal structures. Several other structures, such as the descending colon, are also referred to as being retroperitoneal, but they remain separated from the other retroperitoneal structures by a clearly defined fascial plane, which corresponds with the plane of fusion of their mesentery during development. This is of relevance during surgical exposure of the retroperitoneal organs and in some pathological processes: those defined by clear fascial planes may be mobilized with little or no risk of bleeding, whereas mobilization of the pancreas, for example, is difficult and often very vascular.
Fig. 62.1 Fascial layers of the upper posterior abdominal wall. **A**, Transverse section just below the level of the hilum of the kidney. For clarity, the deep muscles of the back have not been identified separately. **B**, The separate layers of the thoracolumbar fascia.
SKIN AND SOFT TISSUES

The skin of the back in the region of the posterior abdominal wall is similar to that of the rest of the trunk. It is supplied by vessels from the musculocutaneous branches of the lumbar arteries and veins, and receives its innervation from the dorsal rami of the lumbar spinal and lower thoracic nerves.

The soft tissues of the posterior abdominal wall and retroperitoneum are composed of several distinct layers of fascia, which divide them into anatomically distinct compartments.

THORACOLUMBAR FASCIA

The thoracolumbar fascia in the lumbar region is in three layers (Figs 62.1, 62.2, 62.3). The posterior layer is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligaments. The middle layer is attached medially to the tips of the transverse processes of the lumbar vertebrae and the intertransverse ligaments, inferiorly to the iliac crest, and superiorly to the lower border of the 12th rib and the lumbocostal ligament. The anterior layer covers quadratus lumbrorum and is attached medially to the anterior surfaces of the transverse processes of the lumbar vertebrae behind the lateral part of psoas major. Inferiorly, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest. Superiorly, it is attached to the apex and inferior border of the 12th rib and then extends to the transverse process of the first lumbar vertebra, to form the lateral arcuate ligament of the diaphragm. The posterior and middle layers of the thoracolumbar fascia unite at the lateral margin of erector spinae. At the lateral border of quadratus lumbrorum they are joined by the anterior layer, to form the aponeurotic origin of transversus abdominis.

OTHER FASCIAL LAYERS

Psoas fascia

Psoas major is enclosed within a layer of fascia over its anterior surface. The medial border is continuous with the attachments of the muscle to the transverse processes of the lumbar vertebrae, the bodies of the lumbar vertebrae and the tendinous arches. Superiorly, the fascia forms part of the medial arcuate ligament. Laterally, the fascia blends with the fascia over quadratus lumborum in the upper part of the muscle and is continuous with the iliac fascia lower down. It separates the anterior mass of psoas major from the retroperitoneal structures lying on it. The fascia extends down into the thigh. Inflammatory collections arising from the paraspinal tissues or the retroperitoneal tissues that penetrate through the fascia tend to be confined by it, and they may track down the length of the muscle, to appear in the groin where the fascia is thinnest.

Iliac fascia

The iliac fascia is continuous with and indistinguishable from the psoas fascia. The fascia blends with the anterior layer of the thoracolumbar fascia over quadratus lumborum in the upper retroperitoneum. Lower down, it is attached firmly to the inner aspect of the iliac crest and medially to the periosteum of the ilium at the pelvic brim. It is also attached in the abdomen to the iliopectineal eminence.

Perirenal fascia

The perirenal fascia is a multilaminated fascial layer that surrounds the kidney, suprarenal glands, upper ureter and associated fat, which all lie in the perirenal space (see Ch. 74). Although described as having anterior and posterior layers, these are continuous with each other laterally, and give rise to the lateroconal fascia at this point (Figs 62.1–62.3). The posterior layer of the renal fascia is adherent to the fascia over psoas major, the iliac fascia and the anterior layers of the thoracolumbar fascia. In the obese, there may be some loose adipose tissue between these layers, but it is rarely thick. The anterior part of the renal fascia separates the kidney and the perirenal space from the overlying anterior pararenal space and its associated viscera (on the right the duodenum, ascending colon and right colonic mesentery and on the left the duodenum, descending colon and left colonic mesentery). Inferiorly, the perirenal fascia continues down and encloses the ureter. It becomes progressively thinner towards the brim of the pelvis, where it is no longer distinguishable from the loose general connective tissue of the retroperitoneum.

Lateroconal fascia
The lateroconal fascia is formed from the lateral aspect of the perirenal fascia and extends anterolaterally to fuse with the fascia over transversus abdominis. It divides the anterior and posterior pararenal spaces from each other, but is thinnest in the inferior part of the retroperitoneum.
POSTERIOR EXTRAPERITONEAL CONNECTIVE TISSUE

The retroperitoneum usually contains loose connective tissue between the fascial layers. This is particularly true around the renal fascia and anterior to the psoas and iliac fascia. In all but the thinnest individuals, there is some adipose tissue present in these areas, and in the obese it may be markedly thickened. The retroperitoneal arteries and veins lie within this tissue, but the branches of the lumbar plexus of nerves lie deep to it, beneath the iliac and psoas fascia.
BONES

The posterior abdominal wall is supported by the bony structures of the vertebral column and bony pelvis. These include the lower two ribs, the 12th thoracic and five lumbar vertebrae, and the sacrum and ilium, in addition to their interconnecting ligaments.
MUSCLES

The majority of the muscles of the posterior abdominal wall are functionally part of the lower limb or vertebral column. They provide the surface against which the neurovascular structures of the retroperitoneum lie, and they are supported and separated from the majority of the retroperitoneal structures by fascial layers (Figs 62.4, 62.5; see Fig. 62.14).

Quadratus lumborum

Quadratus lumborum is an irregularly shaped quadrilateral muscle, which is broader at its inferior attachment than superiorly.

Attachments

Quadratus lumborum is attached below by aponeurotic fibres to the iliolumbar ligament and the adjacent portion of the iliac crest for approximately 5 cm. The superior attachment is to the medial half of the lower border of the 12th rib, and by four small tendons to the apices of the transverse processes of the upper four lumbar vertebrae. Sometimes it is also attached to the transverse process or body of the 12th thoracic vertebra. Occasionally, a second layer of this muscle is found in front of the first, attached to the upper borders of the transverse processes of the lower three or four lumbar vertebrae and to the lower margin and the lower part of the anterior surface of the 12th rib.

Relations

Anteriorly are the colon (ascending on the right, descending on the left), kidney, psoas major and minor, and diaphragm. The subcostal, iliohypogastric and ilioinguinal nerves lie on the fascia anterior to the muscle, but are bound down to it by the medial continuation of the transversalis fascia.

Vascular supply

Quadratus lumborum is supplied by branches of the lumbar arteries, the arteria
lumbalis ima, the lumbar branch of the iliolumbar artery and branches of the subcostal artery.

**Innervation**

Quadratus lumborum is innervated by the ventral rami of the 12th thoracic and upper three or four lumbar spinal nerves.

**Actions**

Quadratus lumborum fixes the last rib, and acts as a muscle of inspiration by helping to stabilize the lower attachments of the diaphragm. It has been suggested that this action might also provide a fixed base for controlled relaxation of the diaphragm in the precise adjustment of expiration needed for speech and singing. With the pelvis fixed, quadratus acts upon the vertebral column, flexing it to the same side. When both muscles contract, they probably help to extend the lumbar part of the vertebral column.

**Psoas major**

Psoas major has several sites of abdominal attachment. Posteriorly, the attachments are to the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae. The muscle arising from these attachments is referred to as the posterior mass. The muscle also has an anterior mass. It consists of two different sets of attachments. The first part is five slips of muscle attached to the bodies of two adjoining vertebrae and their intervertebral disc (from the 12th thoracic vertebra and the thoracolumbar disc to the body of the fifth lumbar vertebra). The second part is a series of tendinous arches extending across the narrow parts of the bodies of the five lumbar vertebrae between these slips. The upper four lumbar intervertebral foramina bear important relations to these attachments of the muscle. The foramina lie anterior to the transverse processes (the posterior attachments) and posterior to the vertebral bodies, discs and tendinous arches (anterior attachments). The roots of the lumbar plexus therefore enter the muscle directly between the two masses and the plexus is lodged within it. The branches then emerge from the borders and surfaces of psoas major.

**Psoas minor**

Psoas minor is often absent but, when present, lies anterior to psoas major. It arises from the sides of the bodies of the 12th thoracic and first lumbar vertebrae and from the disc between them, and ends in a long, flat tendon attached to the pectineal line and iliopectineal eminence and, laterally, to the iliac fascia.

**Erector spinae**

The muscles of the erector spinae group (see Ch. 42) do not form part of the posterior abdominal wall itself, but are closely associated with the fascial layers of the posterior wall.

**Iliacus**

Iliacus is a triangular sheet of muscle that arises from the superior two-thirds of the concavity of the iliac fossa, the inner lip of the iliac crest, the ventral sacroiliac and
iliolumbar ligaments and the upper surface of the lateral part of the sacrum. It reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint. Most of its fibres converge into the lateral side of the strong tendon of psoas major. It lines the posterior wall of the lesser pelvis formed by the ilium.

Posterior abdominal wall hernias

Herniation through the posterior abdominal wall is extremely rare because the fascial layers usually provide an excellent protection against protrusion of the posterior abdominal viscera, which are relatively immobile. However, the posterior free border of external oblique and the inferior free border of latissimus dorsi create an area of potential weakness, referred to as the lumbar triangle. Spontaneous hernias through this tissue are very rare in the absence of previous surgical access such as a nephrectomy.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

ABDOMINAL AORTA

The abdominal aorta begins at the median, aortic hiatus of the diaphragm, anterior to the inferior border of the 12th thoracic vertebra and the thoracolumbar intervertebral disc (Figs 62.6, 62.7). It descends anterior to the lumbar vertebrae to end at the lower border of the fourth lumbar vertebra, a little to the left of the midline, by dividing into two common iliac arteries. It diminishes rapidly in calibre from above downward, because its branches are large; however, the diameter of the vessel at any given height tends to increase slightly with age. The cadaveric superior and inferior calibres are between 9–14 mm and 8–12 mm, respectively, with little difference between the sexes. The angle of the aortic bifurcation varies widely, particularly in the elderly. It has been suggested that the relationship between aortic size and shape is a possible causative factor in the development of abdominal aortic aneurysm (Newman et al 1971). The reflection of transmitted pressure waves at junctions between vessels (of which the abdominal aorta has many) may focally weaken the intimal lining, e.g. at the aortic bifurcation, pressure oscillations and possibly turbulence may be set up as a result of differences in the luminal diameters of the common iliac arteries, producing reflected waves that may injure the intima of the distal abdominal aorta. The role of the relative calibres of the iliac arteries remains uncertain (Shah et al 1978).
Fig. 62.6 The abdominal aorta, inferior vena cava and their branches. The fasciae, lymphatics and connective tissue have been removed for clarity.
Relations

The upper abdominal aorta is related anteriorly to the coeliac trunk and its branches. The coeliac plexus and the lesser sac lie between it and the left lobe of the liver and lesser omentum. Below this, the superior mesenteric artery leaves the aorta, crossing anterior to the left renal vein. The body of the pancreas, with the splenic vein on its posterior surface, extends obliquely up and to the left across the abdominal aorta, separated from it by the superior mesenteric artery and left renal vein. Below the pancreas, the proximal parts of the gonadal arteries, and the third part of the duodenum, lie anteriorly. In its lowest part it is covered by the posterior parietal peritoneum and crossed obliquely by the origin of the small intestinal mesentery.

The thoracolumbar intervertebral discs, the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament are all posterior to the abdominal aorta. Lumbar arteries arise from its dorsal aspect and cross posterior to it. The third and fourth (and sometimes second) left lumbar veins also cross behind it to reach the inferior vena cava. The aorta may overlap the anterior border of the left psoas major.

On the right, the aorta is related above to the cisterna chyli and thoracic duct, the azygos vein and the right crus of the diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra, it is closely applied to the left side of the inferior vena cava. This close relationship occasionally allows the formation of an aorto-caval fistula, particularly after surgery for aneurysmal disease or trauma to the aorta.

On the left, the aorta is related above to the left crus of the diaphragm and left coeliac ganglion. Level with the second lumbar vertebra, it is related to the duodenojejunal flexure and the left sympathetic trunk, the fourth part of the duodenum and the inferior mesenteric vein.

Branches

The branches of the aorta are described as anterior, lateral and dorsal (Fig. 62.8). The
anterior and lateral branches are distributed to the viscera and the dorsal branches supply the body wall, vertebral column, vertebral canal and its contents. The aorta terminates by dividing into the right and left common iliac arteries.

**Anterior group**

**Coeliac trunk**

The coeliac trunk is the first anterior branch and arises just below the aortic hiatus at the level of T12/L1 vertebral bodies (Fig. 62.9). It is 1.5–2 cm long and passes almost horizontally forwards and slightly right above the pancreas and splenic vein. It divides into the left gastric, common hepatic and splenic arteries. The coeliac trunk may also give off one or both of the inferior phrenic arteries. The superior mesenteric artery may
arise with the coeliac trunk as a common origin. One or more of the superior mesenteric branches may arise from the coeliac trunk. Anterior to the coeliac trunk lies the lesser sac. The coeliac plexus surrounds the trunk, sending extensions along its branches. On the right lie the right coeliac ganglion, right crus of the diaphragm and the caudate lobe of the liver. To the left lie the left coeliac ganglion, left crus of the diaphragm and the cardiac end of the stomach. The right crus may compress the origin of the coeliac trunk, giving the appearance of a stricture. The body of the pancreas and the splenic vein are inferior to the coeliac trunk.

**Fig. 62.9** Volume rendered surface shaded CT angiogram of the major branches of the abdominal aorta (renal, coeliac and superior mesenteric arteries).

*(Courtesy of Dr Nasir Khan, Chelsea & Westminster Hospital, London.)*

**Superior mesenteric artery**
The superior mesenteric artery originates from the aorta approximately 1 cm below the coeliac trunk, at the level of the L1/2 intervertebral disc (Fig. 62.9). It lies posterior to the splenic vein and the body of the pancreas, and is separated from the aorta by the left renal vein. It runs inferiorly and anteriorly, anterior to the uncinate process of the pancreas and the third part of the duodenum.

**Inferior mesenteric artery**

The inferior mesenteric artery is usually smaller in calibre than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the aorta at about the level of the third lumbar vertebra, 3 or 4 cm above the aortic bifurcation and posterior to the horizontal part of the duodenum (Figs 62.6, 62.9).

**Lateral group**

**Suprarenal artery**

The middle suprarenal artery arises from the lateral aspect of the abdominal aorta, level with the superior mesenteric artery. It ascends slightly, and runs over the crura of the diaphragm to the suprarenal glands, where it anastomoses with the suprarenal branches of the phrenic and renal arteries. The right middle suprarenal artery passes behind the inferior vena cava, near the right coeliac ganglion. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas.

**Renal artery**

The renal arteries are two of the largest branches of the abdominal aorta and arise laterally from the vessel just below the origin of the superior mesenteric artery. The right is longer and usually arises slightly higher than the left. It passes posterior to the inferior vena cava, right renal vein, head of the pancreas and second part of the duodenum. The left renal artery arises a little lower down and passes behind the left renal vein, the body of the pancreas and the splenic vein.

**Gonadal artery**

The gonadal arteries are two long, slender vessels that arise from the aorta a little inferior to the renal arteries. Each passes inferolaterally under the parietal peritoneum on psoas major.

**Dorsal group**

**Inferior phrenic arteries**

The inferior phrenic arteries usually arise from the aorta, just above the level of the coeliac trunk. Occasionally they arise from a common aortic origin with the coeliac trunk, from the coeliac trunk itself or from the renal artery. They contribute to the arterial supply of the diaphragm. Each artery ascends and runs laterally anterior to the crus of the diaphragm, near the medial border of the suprarenal gland. The left passes behind the oesophagus and forwards on the left side of its diaphragmatic opening. The right passes posterior to the inferior vena cava and then along the right of the diaphragmatic opening for the inferior vena cava. Near the posterior border of the central tendon of the diaphragm, each divides into medial and lateral branches (Fig.
The medial branch curves forwards to anastomose with its fellow in front of the central tendon and with the musculophrenic and pericardiacophrenic arteries. The lateral branch approaches the thoracic wall, and anastomoses with the lower posterior intercostal and musculophrenic arteries. The lateral branch of the right artery provides the arterial supply to the wall of the inferior vena cava, whereas the left sends ascending branches to the serosal surface of the abdominal oesophagus. Each inferior phrenic artery has two or three small suprarenal branches. The capsule of the liver and spleen may also receive a small supply from the arteries.

**Lumbar arteries**

There are usually four lumbar arteries on each side, in series with the posterior intercostal arteries. They arise from the posterolateral aspect of the aorta, opposite the lumbar vertebrae. A fifth, smaller, pair occasionally arise from the median sacral artery, but lumbar branches of the iliolumbar arteries usually take their place. The lumbar arteries run posterolaterally on the first to the fourth lumbar vertebral bodies, behind the sympathetic trunks, to intervals between the lumbar transverse processes. From here they continue into the muscles of the posterior abdominal wall. The right arteries pass posterior to the inferior vena cava. The upper two on the right side, and the first left lumbar arteries, lie posterior to the corresponding crus of the diaphragm. Arteries of both sides pass under tendinous arches, which span the lateral concavities of the vertebral bodies, and which form the attachment of psoas major. The arteries run posterior to the muscle and the lumbar plexus, then cross the anterior surface of quadratus lumborum. At the lateral border of quadratus lumborum they pierce the posterior aponeurosis of transversus abdominis, and run forwards between it and internal oblique. They anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

**Dorsal branches**

Each lumbar artery has a dorsal branch, which passes backwards between the adjacent transverse vertebral processes to supply the dorsal muscles of the back, the joints and skin of the back. This branch also has a spinal branch which enters the vertebral canal to supply its contents and adjacent vertebra, anastomosing with the arteries above and below it and across the midline (see Fig. 43.9). The spinal branch of the first lumbar artery supplies the terminal part of the spinal cord proper and the remainder supply the cauda equina, meninges and vertebral canal. Occlusion of all or most of these arteries by dissection or aneurysm of the abdominal aorta may cause ischaemia of the cauda equina, producing the so-called ‘cauda equina syndrome’. This is rare, however, even after infrarenal aortic graft surgery, because of the relatively good collateral circulation of the spinal cord arteries from the descending thoracic aorta. Branches of the lumbar arteries and their dorsal branches supply the adjacent muscles, fasciae, bones, haemopoietic marrow, ligaments and joints of the vertebral column.

**Median sacral artery**

The median sacral artery is a small branch that arises from the posterior aspect of the aorta a little above its bifurcation. It descends in the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx, and ends in the coccygeal body. At the level of the fifth lumbar vertebra, it is crossed by the left common iliac vein and often gives off a small lumbar artery (arteria lumbalis ima), small branches of which reach
the anorectum via the anococcygeal ligament. Anterior to the fifth lumbar vertebra the median sacral artery anastomoses with a lumbar branch of the iliolumbar artery. Anterior to the sacrum it anastomoses with the lateral sacral arteries and sends branches into the anterior sacral foramina.
INFERIOR VENA CAVA

The inferior vena cava conveys blood to the right atrium from all structures below the diaphragm (Fig. 62.10). The majority of its course is within the abdomen, but a small section lies within the fibrous pericardium in the thorax.

Fig. 62.10 Multislice computed tomography three-dimensional surface-shaded angiogram of the abdominal aorta and inferior vena cava.
The inferior vena cava is formed by the junction of the common iliac veins anterior to the fifth lumbar vertebral body, a little to its right. It ascends anterior to the vertebral column, to the right of the aorta, and is contained in a deep groove on the posterior surface of the liver, or sometimes in a tunnel completed by a band of liver tissue. It next crosses the tendinous part of the diaphragm between its median and right ‘leaves’, inclines slightly anteromedially and passes through the fibrous pericardium and a posterior inflexion of the serous pericardium to open into the inferoposterior part of the right atrium. The abdominal portion of the inferior vena cava is devoid of valves.

**Relations of the abdominal part of the inferior vena cava**

Anteriorly, the inferior vena cava is related to the right common iliac artery at its origin. It is crossed obliquely by the root of the mesentery and its contained vessels and nerves, and by the right gonadal artery. It lies behind the peritoneum of the posterior abdominal wall and the third part of the duodenum, and ascends behind the head of the pancreas and then the first part of the duodenum, separated from these structures by the common bile duct and portal vein. Above the duodenum it is again covered by the peritoneum of the posterior abdominal wall, which forms the posterior wall of the epiploic foramen and which separates the inferior vena cava from the right free border of the lesser omentum and its contents. Above this it is intimately related to the liver anteriorly.

The lower three lumbar vertebral bodies and their intervertebral discs, the anterior longitudinal ligament, right psoas major, sympathetic trunk and third and fourth lumbar arteries, are all posterior to the inferior vena cava. Superior to these structures, the inferior vena cava is related posteriorly to the right crus of the diaphragm, the medial part of the right suprarenal gland, the right coeliac ganglion and the right renal, middle suprarenal and inferior phrenic arteries.

The right ureter, the second part of the duodenum, medial border of the right kidney and the right lobe of the liver are all lateral to the right side of the inferior vena cava. The aorta, the right crus of the diaphragm and the caudate lobe of the liver are all lateral to the left side.

Numerous anomalies may occur in the anatomy of the inferior vena cava, mostly related to its complex formation. It is sometimes replaced, below the level of the renal veins, by two more or less symmetric vessels (Fig. 62.11), often associated with the failure of interconnection between the common iliac veins, and persistence on the left of a longitudinal channel (usually the supracardinal or subcardinal vein) that normally disappears in early fetal life. In complete visceral transposition, the inferior vena cava lies to the left of the aorta.
Tributaries

The abdominal inferior vena cava usually receives the common iliac veins at its origin and the lumbar, right gonadal, renal, right suprarenal, inferior phrenic and hepatic veins during its course (Figs 62.6, 62.12).
Lumbar veins

Four pairs of lumbar veins collect blood by dorsal tributaries from the lumbar muscles and skin. These branches anastomose with tributaries of the lumbar origin of the azygos and hemiazygos veins. The abdominal tributaries to the lumbar veins drain blood from the posterior, lateral and anterior abdominal walls, including the parietal peritoneum. Anteriorly, the abdominal tributaries
anastomose with branches of the inferior and superior epigastric veins. These anastomoses provide routes of continued venous drainage from the pelvis and lower limb to the heart in the event of inferior vena caval obstruction. The abdominal tributaries drain into the superior epigastric veins and hence via the internal thoracic veins to the superior vena cava, whereas the dorsal tributaries carry blood into the azygos and hemiazygos system and hence into the superior vena cava. Near the vertebral column, the lumbar veins drain the vertebralplexuses and are connected by the ascending lumbar vein, which is a vessel running longitudinally anterior to the roots of the transverse processes of the lumbar vertebrae. The third and fourth lumbar veins are fairly consistent in their course, and usually pass forward on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava. The left lumbar veins pass behind the abdominal aorta and are therefore longer. First and second lumbar veins are much more variable; they may drain into the inferior vena cava, ascending lumbar vein, or lumbar azygos veins, and are often connected to each other. The first lumbar vein does not usually enter the inferior vena cava directly, but either turns down to join the second lumbar vein or, less commonly, may drain directly into the ascending lumbar vein or pass forward over the first lumbar vertebral body to join the lumbar azygos vein. The second lumbar vein may join the inferior vena cava at or near the level of the renal veins, or, less commonly, join the third lumbar or ascending lumbar vein.

Ascending lumbar vein

The ascending lumbar vein connects the common iliac, iliolumbar and lumbar veins. It lies between psoas major and the roots of the lumbar transverse processes. There is considerable variability in the course of this vein and the related lumbar azygos and first lumbar veins. Superiorly, it commonly joins the subcostal vein to form the azygos vein on the right and the hemiazygos on the left. These veins run forward over the 12th thoracic vertebral body, and pass deep to the crura of the diaphragm and into the thorax. The ascending lumbar vein is usually joined by a small vessel from the back of the inferior vena cava or left renal vein on the left. This little vein represents the azygos line and is referred to as the lumbar azygos vein. Sometimes the ascending lumbar vein ends in the first lumbar vein, which then skirts the first lumbar vertebra with the first lumbar artery, to join the lumbar azygos vein. In this circumstance the subcostal veins join the azygos vein on the right and the hemiazygos vein on the left.

Gonadal veins

Only the right gonadal vein joins the inferior vena cava directly. It opens into its right anterolateral aspect at an acute angle just inferior to the level of the left renal vein. It is often double all the way to the level of entry into the inferior vena cava.
Renal veins

The renal veins are large calibre vessels, which lie anterior to the renal arteries and open into the inferior vena cava almost at right angles (Fig. 62.10). The left is three times longer than the right in length (7.5 cm and 2.5 cm, respectively). The left vein lies on the posterior abdominal wall posterior to the splenic vein and body of the pancreas. Close to its opening into the inferior vena cava, it lies anterior to the aorta with the superior mesenteric artery just above it. The right renal vein lies posterior to the second part of the duodenum and sometimes the lateral part of the head of the pancreas.

Suprarenal vein

The right suprarenal vein drains directly into the inferior vena cava at the level of the 12th thoracic vertebra.

Inferior phrenic veins

The inferior phrenic veins run on the inferior surface of the central tendon of the diaphragm. They drain into the posterolateral aspect of the inferior vena cava around the level of the tenth thoracic vertebra. The left vein tends to drain at a slightly higher level than the right, and runs above the level of the oesophageal opening in the diaphragm. It may be double, with a branch draining into the left renal or suprarenal vein.

Collaterals in inferior vena caval occlusion

Oclusion of the inferior vena cava may follow thrombosis resulting from hypercoagulable conditions, or embolism from lower limb or pelvic thromboses. Collateral venous circulation is established through a wide range of anastomoses between branches that drain ultimately to the superior vena cava. The lumbar veins connect to branches of the superior and inferior epigastric, circumflex iliac, lateral thoracic, subcostal and posterior intercostal veins. They also anastomose with tributaries of the azygos, hemiazygos and lumbar azygos veins. The interconnecting vertebral venous plexuses provide an additional route of collateral circulation between the vena cavae.

Inferior vena caval filters

Recurrent embolization of clot from the pelvic or lower limbs veins may be a serious threat to life. In an effort to prevent life-threatening pulmonary embolism, a fenestrated filter may be placed within the inferior vena cava in an effort to trap the clot. These are most commonly inserted by radiological guidance via the internal jugular vein and superior vena cava and placed at a level below the origin of the renal veins. Progressive occlusion of the filter by clot may lead to symptoms of vena caval obstruction. Rarely, damage to the medial wall of the vena cava from the retaining hooks of the filter may lead to
the development of an aorto-caval fistula as a result of the close proximity of
the aorta at this level.
LYMPHATIC DRAINAGE

The lymphatic drainage of the muscles, deep tissues and integument of the posterior abdominal wall is broadly divided into four regions. The small upper left and upper right regions drain to the lateral aortic nodes and the ipsilateral axillary lymph nodes. The larger lower left and lower right portions drain to the lateral and retro-aortic lymph nodes, although some drainage also occurs to the left and right superficial inguinal nodes.

The lymphatic drainage of the abdominal viscera occurs almost exclusively through the cisterna chyli and the thoracic duct. Some lymphatic drainage may occur across the diaphragm from the bare area of the liver and the uppermost retroperitoneal tissues, but this is probably of little clinical consequence other than during obstruction of the thoracic duct. The lymph nodes of the retroperitoneum lie around the abdominal aorta and form pre-aortic, lateral aortic and retro-aortic groups (Fig. 62.13). Collectively, they are referred to as the para-aortic lymph nodes and clinically it is difficult to distinguish between them, either at operation or on cross-sectional imaging.
**Cisterna chyli and abdominal lymph trunks**

The abdominal origin of the thoracic duct lies to the right of the midline at the level of the lower border of the 12th thoracic vertebral body or the thoracolumbar intervertebral disc. It receives all the lymph delivered by the four main abdominal lymph trunks, which converge to an elongated arrangement of channels, referred to as the abdominal confluence of lymph.
trunks. The confluence may be a simple duct-like structure or be duplicated, triplicated or plexiform. When it is wider than the thoracic duct, its interior is sometimes irregular and bilocular or trilocular, and it may surround intercalated lymph nodes. Occasionally the confluence is a simple, fusiform, saccular dilatation; the widely used name ‘cisterna chyli’ best describes these simpler forms.

The abdominal confluence of lymph trunks extends from the beginning of the thoracic duct, vertically downwards for 5–7 cm, and lies anterolateral to the right of the first and second lumbar vertebral bodies and their intervening discs. It lies immediately to the right of the abdominal aorta. Along its length it lies between the territories containing the upper right lateral aortic lymph nodes and right-sided members of the coeliac and superior mesenteric pre-aortic groups, branches from which may drain directly into the various trunks. The upper two right lumbar arteries and the right lumbar azygos vein are between the confluence and the vertebral column. The medial edge of the right crus of the diaphragm lies anterior to the abdominal confluence of lymph trunks. The confluence receives the right and left lumbar and intestinal lymph trunks, although rarely these may drain directly into the thoracic duct.

The lumbar lymph trunks are formed by vessels draining from the lateral aortic nodes. Thus, either directly, or after traversing intermediary groups, the trunks carry lymph from the lower limbs, the full thickness of the pelvic, perineal and infra-umbilical abdominal walls, the deep tissues of most of the supra-umbilical abdominal walls, most of the pelvic viscera, gonads, kidneys and suprarenal glands. The intestinal lymph trunks receive vessels draining from coeliac nodes and, via these nodes, the superior and inferior mesenteric nodes, which are collectively the pre-aortic nodes. Either directly or via intermediary groups, they drain the entire abdominal gastrointestinal tract down to the anus.

The intimate relationship of the cisterna chyli and abdominal lymph trunks to the abdominal aorta may lead to problems after aortic surgery, particularly dissections carried out around the aorta above the level of the coeliac axis. The large calibre of the trunks, coupled with the volume of lymph flowing through them, means that they do not readily self-seal after injury, and this may lead to problematic recurrent chylous (lymphatic) ascites.

The thoracic duct leaves the superior end of the cisterna chyli or the abdominal confluence and immediately passes through the aortic aperture of the diaphragm posterolateral to the aorta.

Pre-aortic group

The pre-aortic groups tend to lie around the origins of the anterior (visceral) arteries and receive lymph from the gastrointestinal tract and its accessory
structures (liver, spleen and pancreas) from the abdominal oesophagus to the level of the anus. They give rise to lymphatic vessels, which drain upwards to form the intestinal trunks that enter the abdominal confluence of lymph trunks. They are divisible into coeliac, superior mesenteric and inferior mesenteric groups, being near the origins of these arteries.

**Coeliac nodes**

The coeliac nodes lie anterior to the abdominal aorta around the origin of the coeliac artery. They are a terminal group and receive lymph draining from the regional lymph nodes around the branches of the coeliac artery (left gastric, hepatic and pancreaticsplenic nodes) and from the lower pre-aortic groups (the superior mesenteric and inferior mesenteric). The coeliac nodes give rise to right and left intestinal lymph trunks.

**Gastric**

There are numerous gastric lymph node groups. They drain the stomach, upper duodenum, abdominal oesophagus and the greater omentum into the coeliac group.

**Hepatic**

The hepatic nodes extend in the lesser omentum along the hepatic arteries and bile duct. They vary in number and site, but almost always occur at the junction of the cystic and common hepatic ducts (the cystic node), alongside the upper common bile duct and in the anterior border of the epiploic foramen. Hepatic nodes drain the majority of the liver, gallbladder and bile ducts, but also receive drainage from some parts of the stomach, duodenum and pancreas. They drain into the coeliac nodes and thence to the intestinal trunks.

**Pancreaticsplenic**

The pancreaticsplenic nodes drain the spleen, pancreas and part of the stomach into the coeliac nodes.

**Superior mesenteric and inferior mesenteric nodes**

The superior and inferior mesenteric nodes lie anterior to the aorta near the origins of their respective arteries. The superior and inferior mesenteric nodes are preterminal groups for the alimentary canal from the duodenojejunal flexure to the upper anal canal. They collect from outlying groups, including the mesenteric, ileocolic, colonic and pararectal nodes and drain into the coeliac nodes.

**Lateral aortic group**
The lateral aortic nodes lie on either side of the abdominal aorta anterior to the medial margins of psoas major, diaphragmatic crura and sympathetic trunks. On the right, some nodes lie lateral and anterior to the inferior vena cava near the end of the right renal vein. Nodes rarely lie between the aorta and inferior vena cava where they are closely related. The lateral aortic nodes drain the viscera and other structures supplied by the lateral and dorsal aortic branches. The upper lateral groups receive the lymph drainage directly from the suprarenal glands, kidneys, ureters, gonads, uterine tubes and upper uterus. They also receive lymph directly from the deeper tissues of the posterior abdominal wall. Lymphatics from the pelvis, most of the pelvic viscera, the perineum and the anterolateral abdominal wall pass first to regional nodes largely related to the iliac arteries and their branches. These include the common iliac, external iliac, internal iliac and circumflex iliac nodes, in addition to the inferior epigastric and sacral nodes. Lymph from the lower limbs passes through the pelvic lymph nodes via the iliac groups.

The lateral aortic group drains into the two lumbar lymph trunks, one on each side, which terminate in the confluence of lymph trunks. A few vessels may pass to the pre-aortic and retro-aortic nodes and others cross the midline to flow into the contralateral nodes, forming a loose plexus.

Retro-aortic group

The retro-aortic group is the smallest of all the para-aortic lymph nodes and has no particular areas of drainage, although it may receive some lymph directly from the paraspinal posterior abdominal wall. Retro-aortic nodes are effectively peripheral nodes of the lateral aortic groups and provide interconnections between surrounding groups.
INNERVATION

The posterior abdominal wall contains the origin of the lumbar plexus and numerous autonomic plexuses and ganglia, which lie close to the abdominal aorta and its branches (Fig. 62.14).

The lumbar ventral rami descend laterally into psoas major, and increase in size from first to last. The first three and most of the fourth form the lumbar plexus; the smaller moiety of the fourth joins the fifth as a lumbosacral trunk, which joins the sacral plexus. The fourth ramus is often termed the nervus furcalis, because it is divided between the two plexuses. Occasionally the third ramus is the nervus furcalis, and both third and fourth ventral rami may be furcal nerves, in which case the plexus is termed prefixed. More frequently, the fifth ventral ramus is furcal, and the plexus is then termed postfixed. These variations modify the sacral plexus.

The first and second, and sometimes the third, lumbar ventral rami are each connected with the lumbar sympathetic trunk by a white ramus communicans. All lumbar ventral rami are joined near their origins by long slender grey rami communicantes from the four lumbar sympathetic ganglia. The rami communicantes accompany the lumbar arteries round the sides of the vertebral bodies, behind psoas major. Their arrangement is irregular: one ganglion may give rami to two lumbar ventral rami, or one lumbar ventral ramus may receive rami from two ganglia, or grey rami often leave the sympathetic trunk between ganglia.

LUMBAR PLEXUS

The lumbar plexus lies within the substance of the posterior part of psoas major, anterior to the transverse processes of the lumbar vertebrae and in ‘line’ with the intervertebral foramina (Fig. 62.15). It is formed by the first three, and most of the fourth, lumbar ventral rami, with a contribution from the 12th thoracic ventral ramus. Although there may be minor variations, the most common arrangement of the plexus is described here.
The first lumbar ventral ramus, joined by a branch from the 12th thoracic ventral ramus, bifurcates, and the upper and larger part divides again into the iliohypogastric and ilioinguinal nerves. The smaller lower part unites with a branch from the second lumbar ventral ramus to form the genitofemoral nerve. The remainder of the second, third, and part of the fourth, lumbar ventral rami join the plexus and divide into ventral and dorsal branches. Ventral branches of the second to fourth rami join to form the obturator nerve.
The main dorsal branches of the second to fourth rami join to form the femoral nerve. Small branches from the dorsal branches of the second and third rami join to form the lateral femoral cutaneous nerve. The accessory obturator nerve, when it exists, arises from the third and fourth ventral branches. The lumbar plexus is supplied by branches from the lumbar vessels which supply psoas major.

The branches of the lumbar plexus are:

Division of constituent ventral rami into ventral and dorsal branches is not as clear in the lumbar and lumbosacralplexuses as it is in the brachial plexus. Anatomically, the obturator and tibial nerves (via the sciatic) arise from ventral divisions, and the femoral and fibular nerves (via the sciatic) from dorsal divisions. Lateral branches of the 12th thoracic and first lumbar ventral rami are drawn into the gluteal skin, but otherwise these nerves are typical. The second lumbar ramus is difficult to interpret. It not only contributes substantially to the femoral and obturator nerves, but also has an anterior terminal branch (the genital branch of the genitofemoral) and a lateral cutaneous branch (lateral femoral cutaneous nerve and the femoral branch of the genitofemoral). Anterior terminal branches of the third to fifth lumbar and first sacral rami are suppressed, but the corresponding parts of the second and third sacral rami supply the skin, etc. of the perineum.

Inflammatory processes may occur in the posterior abdominal wall in the tissues anterior to psoas major, such as retrocaecal appendicitis on the right and diverticular abscess on the left. This may cause irritation of one or more of the branches of the lumbar plexus and lead to presenting symptoms of pain or dysesthesia in the distribution of the affected nerves such as in the thigh, hip or buttock skin.

**Muscular branches**

Small branches from all five lumbar roots.

**Iliohypogastric nerve**
Distribution

The iliohypogastric nerve originates from the L1 ventral ramus. It emerges from the upper lateral border of psoas major, crosses obliquely behind the lower renal pole and in front of quadratus lumborum. Above the iliac crest, it enters the posterior part of transversus abdominis. Between transversus abdominis and internal oblique, it divides into lateral and anterior cutaneous branches, and also supplies both muscles. The lateral cutaneous branch runs through internal and external oblique above the iliac crest, a little behind the iliac branch of the 12th thoracic nerve, and is distributed to the posterolateral gluteal skin. The anterior cutaneous branch runs between and supplies internal oblique and transversus abdominis. It runs through internal oblique approximately 2 cm medial to the anterior superior iliac spine, and through the external oblique aponeurosis approximately 3 cm above the superficial inguinal ring, and is then distributed to the suprapubic skin. The iliohypogastric nerve connects with the subcostal and ilioinguinal nerves (see Fig. 61.4). The nerve is occasionally injured during an oblique surgical approach to the appendix, but there is rarely any detectable sensory loss because the suprapubic skin is innervated from several sources. Division of the iliohypogastric nerve above the anterior superior iliac spine may weaken the posterior wall of the inguinal canal and predispose to formation of a direct hernia.

Motor

The iliohypogastric nerve supplies a small motor contribution to transversus abdominis and internal oblique, including the conjoint tendon.

Sensory

The iliohypogastric nerve supplies sensory fibres to transversus abdominis, internal oblique and external oblique, and innervates the posterolateral gluteal and suprapubic skin.

Ilioinguinal nerve

Distribution

The ilioinguinal nerve originates from the L1 ventral ramus. It is usually smaller than the iliohypogastric nerve and arises with it from the first lumbar ventral ramus, to emerge from the lateral border of psoas major, with or just inferior to the iliohypogastric nerve. It passes obliquely across quadratus lumborum and the upper part of iliacus and enters transversus abdominis near the anterior end of the iliac crest, where it sometimes connects with the iliohypogastric nerve. At this point it can readily be affected by a relatively small volume of local anaesthetic to help anaesthetize the inguinal canal for surgery. It pierces internal oblique a little lower down, supplies it and then
traverses the inguinal canal below the spermatic cord. It emerges with the cord from the superficial inguinal ring and supplies the proximal medial skin of the thigh and the skin over the root of the penis and upper part of the scrotum in males, or the skin covering the Mons pubis and the adjoining labium majus in females. The ilioinguinal and iliohypogastric nerves are reciprocal in size. The ilioinguinal is occasionally very small and ends by joining the iliohypogastric, a branch of which then takes its place. Occasionally, the ilioinguinal nerve is completely absent, in which case the iliohypogastric nerve supplies its territory. The nerve may be injured during inguinal surgery, particularly for hernia, which produces paraesthesia over the skin of the genitalia. Entrapment of the nerve during surgery may cause troublesome recurrent pain in this distribution.

Motor

The ilioinguinal nerve supplies motor nerves to transversus abdominis and internal oblique.

Sensory

The ilioinguinal nerve supplies sensory fibres to transversus abdominis and internal oblique. It innervates the medial skin of the thigh and the skin over the root of the penis and upper part of the scrotum in males or the skin covering the Mons pubis and the adjoining labium majus in females.

Genitofemoral nerve

Distribution

The genitofemoral nerve originates from the L1 and L2 ventral rami and is formed within the substance of psoas major. It descends obliquely forwards through the muscle to emerge on its abdominal surface near the medial border, opposite the third or fourth lumbar vertebra. It then descends beneath the peritoneum on psoas major, crosses obliquely behind the ureter and divides above the inguinal ligament into genital and femoral branches; it often divides close to its origin, in which case its branches emerge separately from psoas major. The genital branch crosses the lower part of the external iliac artery, enters the inguinal canal by the deep ring and supplies cremaster and the skin of the scrotum in males. In females, it accompanies the round ligament and ends in the skin of the Mons pubis and labium majus. The femoral branch descends lateral to the external iliac artery, and sends a few filaments round it before crossing the deep circumflex iliac artery, passing behind the inguinal ligament and entering the femoral sheath lateral to the femoral artery. It pierces the anterior layer of the femoral sheath and fascia lata and supplies the skin anterior to the upper part of the femoral triangle. It connects with the femoral intermediate cutaneous nerve and supplies the femoral artery. Like the ilioinguinal nerve, the genital branch may be injured.
during inguinal surgery.

Motor

The genitofemoral nerve innervates cremaster via the genital branch.

Cutaneous

The genitofemoral nerve innervates the skin of the scrotum in males or mons pubis and labium majus in females via the genital branch, and the anteromedial skin of the thigh via the femoral branch.

Femoral nerve

The femoral nerve descends through psoas major and emerges low on its lateral border. It passes between psoas major and iliacus deep to the iliac fascia and runs posterior to the inguinal ligament into the thigh. It gives off branches which supply iliacus and pectineus and sends sensory fibres to the femoral artery. Posterior to the inguinal ligament, it lies lateral to the femoral artery and is separated from it by a part of psoas major. The further course and distribution of the femoral nerve is described in Chapter 80.

Lateral femoral cutaneous nerve of the thigh

The lateral femoral cutaneous nerve of the thigh emerges from the lateral border of psoas major and crosses iliacus obliquely towards the anterior superior iliac spine. It supplies sensory fibres to the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the iliac fascia and peritoneum. The left nerve passes behind the lower part of the descending colon. Both nerves pass behind or through the inguinal ligament approximately 1 cm medial to the anterior superior iliac spine and anterior to, or through, sartorius into the thigh. The further course and distribution of the lateral femoral cutaneous nerve is described in Chapter 80.

Obturator nerve

The obturator nerve descends within the substance of psoas major to emerge from its medial border at the level of the pelvic brim. It passes posterior to the common iliac vessels and lateral to the internal iliac vessels. It then descends on the lateral wall of the pelvis attached to the fascia over obturator internus and lies anterosuperior to the obturator vessels before running into the obturator foramen to enter the thigh. It has no branches in the abdomen or pelvis. The further course and distribution of the obturator nerve is described in Chapter 80.

Accessory obturator nerve
When present, the accessory obturator nerve emerges from the medial border of psoas major and runs along this border over the posterior surface of the superior pubic ramus posterior to pectineus. It gives off branches here to supply pectineus and the hip joint, and it may join with the main obturator nerve.
LUMBOSACRAL PLEXUS

The lumbosacral plexus provides the nerve supply to the pelvis and lower limb, in addition to part of the autonomic supply to the pelvic viscera. It gives origin to the sciatic, inferior gluteal, superior gluteal and pudendal nerves and the nerves to quadratus femoris, obturator internus and the posterior cutaneous nerve of the thigh. The further course and distribution of these nerves is described in Chapter 80.
LUMBAR SYMPATHETIC SYSTEM

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia lying on the extraperitoneal connective tissue anterior to the vertebral column and along the medial margin of psoas major. Superiorly, it is continuous with the thoracic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac artery and is continuous with the pelvic sympathetic trunk. On the right side, it lies posterior to inferior vena cava, and on the left it is posterior to the lateral aortic lymph nodes. It is anterior to most of the lumbar vessels, but may pass behind some lumbar veins.
LUMBAR PARASYMPATHETIC SYSTEM

The parasympathetic supply to the abdominal viscera is provided by the vagus nerve to the coeliac and superior mesenteric plexuses, and from the pelvic splanchnic nerves to the inferior mesenteric, superior hypogastric and inferior hypogastric plexuses.
PARA-AORTIC BODIES

The para-aortic bodies are condensations of chromaffin tissue that are found in close relation to the aortic autonomic plexuses and lumbar sympathetic chains. They are largest in the fetus, become relatively smaller in childhood and have largely disappeared by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the aorta in the region of the intermesenteric, inferior mesenteric and superior hypogastric plexuses. They may lie as high as the coeliac plexus, as low as the inferior hypogastric plexus in the pelvis, or may be closely applied to the sympathetic ganglia of the lumbar chain. Scattered cells that persist into adulthood may, rarely, be the sites of development of tumours of the chromaffin tissue (phaeochromocytoma), although these are much more commonly found arising from the cells of the suprarenal medulla. The wide variation in site of persistent para-aortic body tissue accounts for the range of locations of such tumours.
REFERENCES

*Both this and the Newman reference describe the anatomical factors that may affect the development of aortoiliac atherosclerosis.*
CHAPTER 63 – True pelvis, pelvic floor and perineum

TRUE PELVIS AND PELVIC FLOOR

The true pelvis is a bowl-shaped structure formed from the sacrum, pubis, ilium, ischium, the ligaments which interconnect these bones and the muscles which line their inner surfaces. The true pelvis is considered to start at the level of the plane passing through the promontory of the sacrum, the arcuate line on the ilium, the iliopectineal line and the posterior surface of the pubic crest. This plane, or 'inlet' lies at an angle of between 35 and 50° up from the horizontal and above this the bony structures are sometimes referred to as the false pelvis. They form part of the walls of the lower abdomen. The floor or 'outlet' of the true pelvis is formed by the muscles of levator ani. Although the floor is gutter shaped, it generally lies in a plane between 5 and 15° up from the horizontal. This difference between the planes of the inlet and outlet is the reason why the true pelvis is said to have an axis (lying perpendicular to the plane of both inlet and outlet) which progressively changes through the pelvis from above downwards. The details of the topography of the bony and ligamentous pelvis are considered fully on page 1358.

MUSCLES AND FASCIAE OF THE PELVIS

Pelvic muscles

The muscles arising within the pelvis form two groups. Piriformis and obturator internus, although forming part of the walls of the pelvis, are considered as primarily muscles of the lower limb (Fig. 63.1). Levator ani and coccygeus form the pelvic diaphragm and delineate the lower limit of the true pelvis (Fig. 63.2). The fasciae investing the muscles are continuous with visceral pelvic fascia above, perineal fascia below and obturator fascia laterally.
Fig. 63.1 Piriformis, obturator internus and the ligaments of the pelvis. Those muscles relating only to the pelvis or perineum have been omitted for clarity.

(Adapted from Drake, Vogl and Mitchell 2005.)
Fig. 63.2 Muscles of the female pelvis. The superior gluteal and obturator vessels and nerves as well as the pelvic viscera have been omitted for clarity.

(Adapted from Drake, Vogl and Mitchell 2005.)

**Piriformis**

The complete description of piriformis is in Chapter 80.

Piriformis (see p. 1371) forms part of the posterolateral wall of the true pelvis and is attached to the anterior surface of the sacrum, the gluteal surface of the ilium near the posterior inferior iliac spine, the capsule of the adjacent sacroiliac joint and sometimes to the upper part of the pelvic surface of the sacrotuberous ligament. It passes out of the pelvis through the greater sciatic foramen. Within the pelvis, the anterior surface of piriformis is related to the rectum (especially on the left), the sacral plexus of nerves...
and branches of the internal iliac vessels. The posterior surface lies against the sacrum.

**Obturator internus**

Obturator internus (see p. 1371) and the fascia over its upper inner (pelvic) surface form part of the anterolateral wall of the true pelvis. It is attached to the structures surrounding the obturator foramen, the inferior ramus of the pubis, the ischial ramus, the pelvic surface of the hip bone below and behind the pelvic brim, and the upper part of the greater sciatic foramen. It also attaches to the medial part of the pelvic surface of the obturator membrane. The muscle is covered by a thick fascial layer and the fibres themselves cannot be seen directly from within the pelvis. This fascia gives attachment to some of the fibres of levator ani and thus only the upper portion of the muscle lies lateral to the contents of the true pelvis, whilst the lower portion forms part of the boundaries of the ischio-anal fossa. In the male, the upper portion lies lateral to the bladder, the obturator and vesical vessels, and the obturator nerve. In the female, the attachments of the broad ligament of the uterus, the ovarian end of the uterine tubes, and the uterine vessels, also lie medial to obturator internus and its fascia.

**Levator ani (ischiococcygeus, iliococcygeus, pubococcygeus)**

Levator ani is a broad muscular sheet of variable thickness which is attached to the internal surface of the true pelvis and forms a large portion of the pelvic floor (Fig. 63.3). The muscle is subdivided into named portions according to their attachments and the pelvic viscera to which they are related. These parts are often referred to as separate muscles, but the boundaries between each part cannot be easily distinguished and they perform many similar physiological functions. The separate parts are referred to as ischiococcygeus, iliococcygeus and pubococcygeus. Pubococcygeus is often subdivided into separate parts according to the pelvic viscera to which they relate (puboperinealis, puboprostaticus or pubovaginalis, puboanalis, puborectalis). Levator ani arises from each side of the walls of the pelvis along the condensation of the obturator fascia (the tendinous arch of levator ani; see below). Fibres from ischiococcygeus attach to the sacrum and coccyx but the remaining parts of the muscle converge in the midline. The fibres of iliococcygeus join by a partly fibrous intersection and form a raphe posterior to the anorectal junction. Closer to the anorectal junction and elsewhere in the pelvic floor, the fibres are more nearly continuous with those of the opposite side and the muscle forms a sling (puborectalis and pubovaginalis or pubourethralis).
Fig. 63.3  Muscles of the female pelvis viewed from above. The sacral nerve roots have been divided close to the sacral foramina. The anorectal junction, vagina and urethra have been divided at the level of the pelvic floor.

The attachments for the ischiococcygeus, iliococcygeus and pubococcygeus parts are as follows.

**Ischiococcygeus**

The ischiococcygeal part may be referred to as a separate muscle, sometimes named coccygeus. It lies as the most posterosuperior portion of levator ani and arises as a triangular musculotendinous sheet with its apex attached to the pelvic surface and tip of the ischial spine. The base of the muscle is attached to the lateral margins of the coccyx and the fifth sacral segment. Ischiococcygeus is rarely absent, but may be nearly completely tendinous rather than muscular. It lies on the pelvic aspect of the sacrospinous ligament and may be fused with it, particularly if it is mostly tendinous. The sacrospinous ligament may represent a degenerate part or an aponeurosis of the muscle since the muscle and ligament are coextensive.

**Iliococcygeus**

The iliococcygeal part is attached to the inner surface of the ischial spine below and anterior to the attachment of ischiococcygeus and to the tendinous arch as far forward as the obturator canal (Fig. 63.2). The most posterior fibres are attached to the tip of the sacrum and coccyx but most join with fibres from the opposite side to form a raphe. This raphe is effectively continuous with the fibroelastic anococcygeal ligament, which is closely applied to its inferior surface and some muscle fibres may attach into the ligament. The raphe provides a strong attachment for the pelvic floor posteriorly and must be divided to allow wide excisions of the anorectal canal during abdominoperineal excisions for malignancy. An accessory slip may arise from the most posterior part and is sometimes referred to as iliolsacralis.

**Pubococcygeus**

The pubococcygeal part is attached to the back of the body of the pubis and passes back almost horizontally. The most medial fibres run directly lateral to the urethra and its sphincter as it passes through the pelvic floor; here the muscle is correctly called the puboperinealis, although due to its close relationship to the upper half of the urethra in both sexes it is often referred to as pubourethralis. The muscle fibres from both sides form part of the urethral sphincter complex together with the intrinsic striated and smooth musculature of the urethra; fibres decussate across the midline.
directly behind the urethra. In males some of these fibres lie lateral and inferior to the prostate and are referred to as puboprostaticus (levator prostaticae). In females, some fibres form the pubourethralis, others run further back to form a sling around the posterior wall of the vagina where they are referred to as pubovaginalis. In both sexes, fibres from this part of pubococcygeus attach to the perineal body; a few elements also attach to the anorectal junction. Some of these fibres, sometimes called puboanalis, decussate and blend with the longitudinal rectal muscle and fascial elements to contribute to the conjoint longitudinal coat of the anal canal. Behind the rectum, some fibres of pubococcygeus form a tendinous intersection as part of the levator raphe, and a thick muscular sling, puborectalis, wraps around the anorectal junction. Some fibres blend with those of the external anal sphincter. Pubourethralis, pubovaginalis/puboprostaticus and puboanalis are sometimes collectively referred to as 'pubovisceralis'.

Relations

The superior, pelvic surface of levator ani is separated only by fascia (superior pelvic diaphragmatic, visceral and extraperitoneal) from the urinary bladder, prostate or uterus and vagina, rectum and peritoneum. Its inferior, perineal, surface forms the medial wall of the ischio-anal fossa and the superior wall of the anterior recess of the fossa, both being covered by inferior pelvic diaphragmatic fascia. The posterior border is separated from the coccyx by areolar tissue. The medial borders of the two levator muscles are separated by the visceral outlet, through which pass the urethra, vagina, and anorectum.

Vascular supply

Levator ani is supplied by branches of the inferior gluteal, inferior vesical and pudendal arteries.

Innervation

Fibres which originate mainly in the second, third and fourth sacral spinal segments reach levator ani from below and above by a variety of routes (Wendell-Smith & Wilson 1991). Most commonly, pubococcygeus is supplied by second and third sacral spinal segments via the pudendal nerve, and ischiococcygeus and iliococcygeus by direct branches of the sacral plexus from the third and fourth sacral spinal segments.

Actions

Pubococcygeus is a lateral compressor of the various visceral canals which cross the pelvic floor. Puborectalis also reinforces the external anal sphincter, helps to create the anorectal angle, and reduces the anteroposterior dimension of the ano-urogenital hiatus. Iliococcygeus and, to a lesser extent, the less muscular ischiococcygeus, assist puborectalis in contributing to anorectal and urinary continence.

Levator ani must relax appropriately to permit expulsion of urine and particularly faeces, and it contracts with abdominal muscles and the abdominothoracic diaphragm to raise intra-abdominal pressure. It forms much of the basin-shaped muscular pelvic diaphragm, which supports the pelvic viscera. Like the abdominothoracic diaphragm, but unlike abdominal muscles, levator ani is also active in the inspiratory phase of quiet respiration. In the pregnant female, the shape of the pelvic floor may help to
direct the fetal head into the anteroposterior diameter of the pelvic outlet.

**Pelvic fasciae**

The pelvic fasciae may be conveniently divided into the parietal pelvic fascia, which mainly forms the coverings of the pelvic muscles, and the visceral pelvic fascia, which forms the coverings of the pelvic viscera and their vessels and nerves (Fig. 63.4).

![Fig. 63.4 Fasciae of the pelvis and perineum. Median sagittal section in the male. The parietal pelvic fascia is shown in black, the mesorectal fascia in brown, the fascial boundaries of the deep perineal space/pouch in green, the peritoneum in blue, the deep abdominal fascia in purple and the subcutaneous abdominal and perineal fascia in red. The visceral perietal fasciae have been omitted for clarity.](image)

**Parietal pelvic fascia**

The parietal pelvic fascia consists of the obturator fascia, the fasciae over piriformis, and over levator ani (the pelvic diaphragm), and the presacral fascia.

**Obturator fascia**

The parietal pelvic fascia on the pelvic (medial) surface of obturator internus is well differentiated. Although in humans it is derived from the degenerate upper portion of the attachment of levator ani, it is usually referred to as the obturator fascia. Above, it is connected to the posterior part of the arcuate line of the ilium, and is continuous
with iliac fascia. Anterior to this, as it follows the line of origin of obturator internus, it is gradually separated from the attachment of the iliac fascia and a portion of the periosteum of the ilium and pubis spans between them. It arches below the obturator vessels and nerve, investing the obturator canal, and is attached anteriorly to the back of the pubis. Behind the obturator canal, the fascia is markedly aponeurotic and gives a firm attachment to levator ani, usually called the tendinous arch of levator ani (arcus tendineus musculi levatoris ani) (see Figs 63.3, 63.13, 63.14). Below the attachment of levator ani, the fascia is thin and is effectively composed only of the epimysium of the muscle and overlying connective tissue; posteriorly it forms part of the lateral wall of the ischio-anal fossa in the perineum, and anteriorly it merges with the fasciae of the muscles of the deep perineal space (see Fig. 63.14), which is continuous with the ischio-anal fossa. The obturator fascia is continuous with the pelvic periosteum and thus the fascia over piriformis.

**Fig. 63.13** Muscles and fasciae of the male perineum – coronal view. The section passes through the bulb of the penis at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The parietal pelvic fascia is shown in black, fascial boundaries of the deep perineal space/pouch in green, the deep perineal fascia in purple and the superficial perineal fascia in red. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the ‘pelvic’ aspect of the deep transverse perinei is very thin and does not form a distinct layer as such in places blending with the parietal pelvic fascia over the inferior aspect of levator ani.
Fig. 63.14 Muscles and fasciae of the female perineum – coronal view. The section passes through the bulb of the clitoris at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The parietal pelvic fascia is shown in black, fascial boundaries of the deep perineal space/pouch in green, the deep perineal fascia in purple and the superficial perineal fascia in red. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the ‘pelvic’ aspect of the deep transverse perinei is very thin and does not form a distinct layer as such in places blending with the parietal pelvic fascia over the inferior aspect of levator ani.

Fascia over piriformis

The fascia over the inner aspect of piriformis is very thin, and fuses with the periosteum on the front of the sacrum at the margins of the anterior sacral foramina. It ensheathes the sacral anterior primary rami which emerge from these foramina: the nerves are often described as lying behind the fascia. The internal iliac vessels lie in front of the fascia over piriformis; their branches draw out sheaths of the fascia and extraperitoneal tissue into the gluteal region, above and below piriformis.

Fascia over levator ani (pelvic diaphragm)

The fascia over levator ani covers both of the surfaces of the pelvic diaphragm. On the lower surface, the thin inferior fascia is continuous with the obturator fascia below the tendinous arch of levator ani laterally. It covers the medial wall of the ischio-anal fossa and blends below with fasciae on the urethral sphincter and the external anal sphincter. On the upper surface, the superior fascia of the pelvic diaphragm is markedly thicker than that over the inferior surface. It is attached anteriorly to the back of the body of the pubis, approximately 2 cm above its lower border, and extends laterally across the superior ramus of the pubis, blending with the obturator fascia and continuing along an irregular line to the spine of the ischium. It is continuous posteriorly with the fascia over piriformis and the anterior sacrococcygeal ligament. Medially, the superior fascia of the pelvic diaphragm blends with the visceral pelvic fascia forming part of the endopelvic fascia.

Arcus tendineus fascia pelvis/white line of the parietal pelvic fascia
Low on the superomedial aspect of the upper fascia over levator ani, a thick white band of condensed connective tissue extends from the lower part of the symphysis pubis to the inferior margin of the spine of the ischium (see Figs 63.4, 63.13, 63.14). Although often referred to as the tendinous arch of the pelvic fascia (arcus tendineus fasciae pelvis), it is really the remnant of the degenerate tendon of illoccocygeus in humans and is best referred to as the white line of the parietal pelvic fascia (Smith 1908). It provides attachment for the condensations of visceral pelvic fascia which provide support to the urethra, bladder and vagina in females (see below).

**Presacral fascia**

The presacral fascia forms a hammock-like structure posterior to the posterior portion of the mesorectal fascia. Laterally it extends to the origin of the fascia over piriformis and the fascia over levator ani (superior pelvic diaphragmatic fascia) with which it blends, and more inferiorly it extends between the white line of the parietal pelvic fascia on either side. Inferiorly, it extends to the anorectal junction, where it fuses with the posterior aspect of the mesorectal fascia and the anooccygeal ligament at the level of the anorectal junction. Superiorly, it can be traced to the origin of the superior hypogastric plexus, where it becomes progressively thinner over the promontory of the sacrum and becomes continuous with the retroperitoneal tissues. The right and left hypogastric nerves and inferior hypogastric plexuses lie on its surface and the presacral veins lie immediately posterior to it. It forms a distinct layer which can be seen both on magnetic resonance images of the pelvis and during surgery. The presacral fascia provides an important landmark because extension of rectal tumours through it significantly reduces the possibility of curative resectional surgery. Dissection in the plane posterior to the fascia may result in bleeding from the presacral veins: because the adventitia of the veins is partly attached to the posterior surface of the fascia, the haemorrhage may be severe (since the veins are unable to contract properly).

**Visceral pelvic fascia**

The visceral pelvic fascia is formed from condensations of connective tissue which are closely associated with the pelvic viscera to which it relates and with the neurovascular structures supplying or running near those organs. In its most inferior and lateral extent, the visceral pelvic fascia is closely related to, and effectively derived from, the superior fascia over the attachment of levator ani (see below), whereas more superiorly and posteriorly, it is derived from part of the fascia over piriformis. The condensations where these fasciae meet are sometimes collectively referred to as the ‘endopelvic fascia’. Further accounts are given of the paravisceral portions of the visceral pelvic fascia (e.g. parametrium, paracolpium) in the chapters describing the organs to which the fascia relates.

Several different condensations of endopelvic fascia are recognized both at operation and by MRI imaging. They provide important support to the pelvic viscera and play a role in continence in both sexes.

In the female, pubourethral ligaments form from periurethral connective tissue and attach to the white line of the parietal pelvic fascia close to its pubic end. A little more laterally, similar tissue exists which may be termed the urethropelvic ligaments, and which insert into the white line over levator ani. These condensations are effectively continuous with connective tissue which runs from the paravaginal tissue to the white
line, and is sometimes referred to as the vaginolevator support or attachment. Since the normal angle of the urethra during standing is nearly 45° to the vertical, these two structures combined can be viewed as providing a ‘hammock-like’ support to the midurethra (DeLancey 1994); some fibres may even decussate across the midline between the urethra and the anterior vaginal wall. The upper portion of the pubourethral ligament blends with the pubovesical and vesicopelvic ligaments (connective tissue around the neck of the urinary bladder), and may contain cholinergically innervated smooth muscle fibres, sometimes referred to as pubovesicalis. In males, pubourethral structures are augmented by the puboprostatic ligament/puboprostaticus. In both sexes, these muscles may have a role in opening the upper urethra and bladder neck during micturition.

There is much less condensation of connective tissue around the rectum, and no similar rectopelvic ligaments exist. The connective tissue over the longitudinal muscles of the rectum is thickened just above the anal hiatus in levator ani and it fuses with the endopelvic fascia and the anococcygeal ligament, sometimes referred to as a rectosacral ligament.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PELVIS

The true pelvis contains the internal iliac arteries and veins and the lymphatics which drain the majority of the pelvic viscera. The common and external iliac vessels and the lymphatics which drain the lower limb lie along the pelvic brim and in the lower retroperitoneum, but are conveniently discussed together with the vessels of the true pelvis.

Arteries of the pelvis

Common iliac arteries

The abdominal aorta bifurcates into the right and left common iliac arteries anterolateral to the left side of the fourth lumbar vertebral body. These arteries diverge as they descend and divide at the level of the sacroiliac joint into external and internal iliac arteries. The external iliac artery is the principal artery of the lower limb. The internal iliac artery provides the principal supply to the walls and viscera of the pelvis, the perineum and the gluteal region.

Right common iliac artery

The right common iliac artery is approximately 5 cm long. It passes obliquely across part of the fourth and the fifth lumbar vertebral bodies, and is crossed anteriorly by the sympathetic rami to the pelvic plexus and, at its division into internal and external iliac arteries, by the ureter. It is covered by the parietal peritoneum, which separates it from the coils of the small intestine. Posteriorly, it is separated from the fourth and fifth lumbar vertebral bodies and their intervening disc by the right sympathetic trunk, the terminal parts of the common iliac veins and the start of the inferior vena cava, the obturator nerve, lumbosacral trunk and iliolumbar artery. Laterally, the inferior vena cava and the right common iliac vein lie superiorly and the right psoas major lies inferiorly. The left common iliac vein is posteromedial, and the left psoas major lateral, to the left common iliac artery.

Left common iliac artery

The left common iliac artery is shorter than the right and is approximately 4 cm long. Lying anterior to it are the sympathetic rami to the pelvic plexus, the superior rectal artery and, at its terminal bifurcation, the ureter. The sympathetic trunk, the fourth and fifth lumbar vertebral bodies and intervening disc, the obturator nerve, lumbosacral trunk and iliolumbar artery are all posterior. The left common iliac vein is posteromedial, and the left psoas major lateral, to the left common iliac artery.

Branches

In addition to the external iliac and internal iliac branches, each common iliac artery also gives small branches to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue. The common iliac artery occasionally gives rise to the iliolumbar artery and accessory or replaced renal arteries if the kidney is low lying.

Internal iliac arteries

Each internal iliac artery, approximately 4 cm long, begins at the common iliac
bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacroiliac joint. It descends posteriorly to the superior margin of the greater sciatic foramen where it divides into an anterior trunk, which continues in the same line towards the ischial spine, and a posterior trunk, which passes back to the greater sciatic foramen. Anterior to the artery are the ureter and, in females, the ovary and fimbriated end of the uterine tube. The internal iliac vein, lumbosacral trunk and sacroiliac joint are posterior. Lateral is the external iliac vein, between the artery and psoas major, and the obturator nerve lying inferior to the vein. The parietal peritoneum is medial, separating it from the terminal ileum on the right and the sigmoid colon on the left. Tributaries of the internal iliac vein are also medial (Fig. 63.5).
In the fetus, the internal iliac artery is twice the size of the external iliac artery and is the direct continuation of the common iliac artery. The main trunk ascends on the anterior abdominal wall to the umbilicus, converging on the contralateral artery, and the two arteries run through the umbilicus to enter the umbilical cord as the umbilical arteries. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical artery; the remainder becomes a fibrous medial umbilical ligament. In males, the patent part (usually the superior vesical artery) usually gives off an artery to the vas deferens.

**Posterior trunk branches**

The branches of the posterior trunk of the internal iliac artery are the iliolumbar, lateral sacral and superior gluteal arteries.

**Iliolumbar artery**

The iliolumbar artery is the first branch of the posterior trunk and ascends laterally anterior to the sacroiliac joint and lumbosacral nerve trunk. It lies posterior to the obturator nerve and external iliac vessels and reaches the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The lumbar branch supplies psoas major and quadratus lumborum and anastomoses with the fourth lumbar artery. It sends a small spinal branch through the intervertebral foramen between the fifth lumbar and first sacral vertebrae, to supply the cauda equina. The iliac branch supplies iliacus; between the muscle and bone it anastomoses with the iliac branches of the obturator artery. A large nutrient branch enters an oblique canal in the ilium. Other branches runs around the iliac crest, contribute to the supply of the gluteal and abdominal muscles, and anastomose with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.

**Lateral sacral arteries**

The lateral sacral arteries are usually double, or if single, divide rapidly into superior and inferior branches. The superior and larger artery passes medially into the first or
second anterior sacral foramen, supplies the sacral vertebrae and contents of the sacral canal, and then leaves the sacrum via the corresponding dorsal foramen to supply the skin and muscles dorsal to the sacrum. The inferior or lateral sacral artery crosses obliquely anterior to piriformis and the sacral anterior spinal rami, then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina and are distributed in the same way as the branches of the superior artery.

Superior gluteal artery

The superior gluteal artery is the largest branch of the internal iliac artery and effectively forms the main continuation of its posterior trunk. It runs posteriorly between the lumbosacral trunk and the first sacral ramus or between the first and second rami, then turns slightly inferiorly, leaving the pelvis by the greater sciatic foramen above piriformis and dividing into superficial and deep branches. In the pelvis it supplies piriformis, obturator internus and a nutrient artery to the ilium. The superficial branch enters the deep surface of gluteus maximus. Its numerous branches supply the muscle and anastomose with the inferior gluteal branches while others perforate the tendinous medial attachment of the muscle to supply the skin over the sacrum, where they anastomose with the posterior branches of the lateral sacral arteries. The deep branch of the superior gluteal artery passes between gluteus medius and the bone, soon dividing into superior and inferior branches. The superior branch skirts the superior border of gluteus minimus to the anterior superior iliac spine and anastomoses with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The inferior branch runs through gluteus minimus obliquely, supplies it and gluteus medius and anastomoses with the lateral circumflex femoral artery. A branch enters the trochanteric fossa to join the inferior gluteal artery and ascending branch of the medial circumflex femoral artery; other branches run through gluteus minimus to supply the hip joint.

The superior gluteal artery occasionally arises directly from the internal iliac artery with the inferior gluteal artery and sometimes from the internal pudendal artery.

Anterior trunk branches

The branches of the anterior trunk of the internal iliac artery are the superior and inferior vesical, middle rectal, vaginal, obturator, uterine, internal pudendal and inferior gluteal.

Superior vesical artery

The superior vesical artery is the first large branch of the anterior trunk. It lies on the lateral wall of the pelvis just below the brim and runs anteroinferiorly medial to the periphery of the posterior surface of the pubis. It supplies the distal end of the ureter, the bladder, the proximal end of the vas deferens and the seminal vesicles. It also gives origin to the umbilical artery in the foetus, which remains as a fibrous cord, the medial umbilical ligament, in the adult. This vessel occasionally remains patent as a small artery supplying the umbilicus.

Inferior vesical artery

The inferior vesical artery may arise as a common branch with the middle rectal
artery. In the female it is often replaced by the vaginal artery. It supplies the bladder, the prostate, the seminal vesicles and the vas deferens.

**Middle rectal artery**

The middle rectal artery is often multiple and may be small. It runs into the lateral fascial coverings of the mesorectum. It occasionally arises close to or in common with the origin of the inferior vesical artery in males.

**Vaginal artery**

In females the vaginal artery may replace the inferior vesical artery. It may arise from the uterine artery close to its origin (Fig. 63.6).

*Fig. 63.6 Arteries of the female pelvis.*

**Obturator artery**
The obturator artery runs anteroinferiorly from the anterior trunk on the lateral pelvic wall to the upper part of the obturator foramen. It leaves the pelvis via the obturator canal and divides into anterior and posterior branches. In the pelvis it is related laterally to the fascia over obturator internus and is crossed on its medial aspect by the ureter and, in the male, by the vas deferens. In the nulliparous female the ovary lies medial to it. The obturator nerve is above the artery, the obturator vein below it. In the pelvis, the obturator artery provides iliac branches to the iliac fossa which supply the bone and iliacus and anastomose with the iliolumbar artery. A vesical branch runs medially to the bladder and sometimes replaces the inferior vesical branch of the internal iliac artery. A pubic branch usually arises just before the obturator artery leaves the pelvis, and ascends over the pubis to anastomose with the contralateral artery and the pubic branch of the inferior epigastric artery.

Outside the pelvis, the anterior and posterior terminal branches encircle the foramen between obturator externus and the obturator membrane. The anterior branch curves anteriorly on the membrane and then inferiorly along its anterior margin to supply branches to obturator externus, pectineus, the femoral adductors and gracilis. It anastomoses with the posterior branch and the medial circumflex femoral artery. The posterior branch follows the posterior margin of the foramen and turns anteriorly on the ischial part to anastomose with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. An acetabular branch enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a branch along the ligament of the femoral head.

Occasionally the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric artery which descends almost vertically to the obturator foramen. It usually lies near the external iliac vein, lateral to the femoral ring, and is rarely injured during inguinal or femoral hernia surgery. Sometimes it curves along the edge of the lacunar part of the inguinal ligament, partly encircling the neck of a hernial sac, and may be inadvertently cut during enlargement of the femoral ring in reducing a femoral hernia.

**Uterine artery**

The uterine artery is an additional branch in females. It is a large artery which arises below the obturator artery on the lateral wall of the pelvis and runs inferomedially into the broad ligament of the uterus.

**Internal pudendal artery (in the pelvis)**

The internal pudendal artery arises just below the origin of the obturator artery. It descends laterally to the inferior rim of the greater sciatic foramen, where it leaves the pelvis between piriformis and ischiococcygeus to enter the gluteal region. It then curves around the dorsum of the ischial spine to enter the perineum by the lesser sciatic foramen. This course effectively allows the nerve to wrap around the posterior limit of levator ani at its attachment to the ischial spine and so gain access to the perineum. In the pelvis the internal pudendal artery crosses anterior to piriformis, the sacral plexus and the inferior gluteal artery. Behind the ischial spine it is covered by gluteus maximus, with the pudendal nerve medial and the nerve to obturator internus lateral to it. The internal pudendal artery gives off several muscular branches in the pelvis and gluteal region which supply adjacent muscles and nerves.
Inferior gluteal artery

The inferior gluteal artery is the larger terminal branch of the anterior internal iliac trunk and principally supplies the buttock and thigh. It descends posteriorly, anterior to the sacral plexus and piriformis but posterior to the internal pudendal artery. It passes between the first and second, or second and third, sacral anterior spinal nerve rami, then between piriformis and ischiococcygeus and runs through the lower part of the greater sciatic foramen to reach the gluteal region. The artery runs inferiorly between the greater trochanter and ischial tuberosity with the sciatic and posterior femoral cutaneous nerves, deep to gluteus maximus. It continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries often arise as a common stem from the internal iliac artery, sometimes with the superior gluteal artery. Inside the pelvis the inferior gluteal artery gives branches to piriformis, ischiococcygeus and iliococcygeus and occasionally contributes to the middle rectal arterial supply. In the male, it may supply vessels to the seminal vesicles and prostate.

External iliac arteries

The external iliac arteries are of larger calibre than the internal iliac arteries. Each artery descends laterally along the medial border of psoas major, from the common iliac bifurcation to a point midway between the anterior superior iliac spine and the symphysis pubis, and enters the thigh posterior to the inguinal ligament to become the femoral artery.

The parietal peritoneum and extraperitoneal tissue separate the right external iliac artery from the terminal ileum and, usually, the appendix, and the left external iliac artery from the sigmoid colon and coils of the small intestine anteromedially. At its origin, the external iliac artery may be crossed by the ureter and is also crossed by the gonadal vessels, the genital branch of the genitofemoral nerve, the deep circumflex iliac vein and the vas deferens (male) or round ligament (female). Posteriorly, the artery is separated from the medial border of psoas major by the iliac fascia. The external iliac vein lies partly posterior to its upper part, but is more medial below. Laterally, it is related to psoas major, which is covered by the iliac and psoas fascia. Numerous lymph vessels and nodes lie on its front and sides.

The external iliac artery is principally the artery of the lower limb and as such has few branches in the pelvis. Apart from very small vessels to psoas major and neighbouring lymph nodes, the artery has no branches until it gives off the deep circumflex iliac and inferior epigastric arteries, which arise near to the point at which it passes under the inguinal ligament.

Deep circumflex iliac artery

The deep circumflex iliac artery branches laterally from the external iliac artery almost opposite the origin of the inferior epigastric artery. It ascends and runs laterally to the anterior superior iliac spine behind the inguinal ligament in a sheath formed by the union of the transversalis and iliac fasciae. There it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the internal lip of the iliac crest. About halfway along the iliac crest it runs through transversus abdominis and then between transversus abdominis and internal oblique to anastomose with the iliolumbar and superior gluteal arteries. It gives off a
large ascending branch at the anterior superior iliac spine which runs between internal oblique and transversus abdominis, supplies both muscles, and anastomoses with the lumbar and inferior epigastric arteries.

**Inferior epigastric artery**

The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament. It curves forwards in the anterior extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring whence it continues as an artery of the anterior abdominal wall.

**Veins of the pelvis**

The true pelvis contains a large number of veins which drain the pelvic walls and most of the viscera contained within the pelvis, and which carry venous blood from the gluteal region, hip and thigh. The external iliac veins, which lie close to the brim of the pelvis, carry the venous drainage from most of the lower limb. There is considerable variation in the venous drainage of the pelvis: although the major veins frequently follow their named arterial counterparts, the small tributaries exhibit a great deal of variation between individuals.

**Common iliac veins**

The common iliac vein is formed by the union of the external and internal iliac veins, anterior to the sacroiliac joints. It ascends obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle with the contralateral vessel to form the inferior vena cava. The right common iliac vein is shorter and more nearly vertical, lying posterior and then lateral to its artery. The right obturator nerve passes posteriorly. The left common iliac vein is longer and more oblique, and lies first medial, then posterior, to its artery. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior rectal vessels. Each vein receives iliolumbar and sometimes lateral sacral veins. The left common iliac vein usually drains the median sacral vein. There are no valves in these veins.

The left common iliac vein occasionally ascends to the left of the aorta to the level of the kidney, where it receives the left renal vein and crosses anterior to the aorta to join the inferior vena cava: this vessel represents the persistent caudal half of the left postcardinal or supracardinal vein.

**Median sacral veins**

The right and left medial sacral veins accompany the corresponding arteries anterior to the sacrum, where they unite to form a single vein which usually ends in the left common iliac vein, but which sometimes ends at the common iliac junction.

**Internal pudendal veins**

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel which ends in the internal iliac vein. They receive veins from the inferior rectal veins and either the penile bulb and scrotum (males) or the clitoris and labia (females).

**Internal iliac vein**
The internal iliac vein is formed by the convergence of several veins above the greater sciatic foramen. It does not have the predictable trunks and branches of the internal iliac artery but its tributaries drain the same territories. It ascends posteromedial to the internal iliac artery to join the external iliac vein, forming the common iliac vein at the pelvic brim, anterior to the lower part of the sacroiliac joint. It is covered anteromedially by parietal peritoneum. Its tributaries are the gluteal, internal pudendal and obturator veins, which originate outside the pelvis; the lateral sacral veins, which run from the anterior surface of the sacrum; and the middle rectal, vesical, uterine and vaginal veins, which originate in the venous plexuses of the pelvic viscera (Fig. 63.7).
The venous drainage of the leg may be blocked by thrombosis involving the external iliac systems and the inferior vena cava. Under these circumstances, the pelvic veins, particularly the internal iliac tributaries, enlarge and provide a major avenue of venous return from the femoral system. Surgical interference with these veins may seriously compromise venous drainage and precipitate oedema of one or both legs.

**Superior gluteal veins**

The superior gluteal veins are the venae comitantes of the superior gluteal artery. They receive tributaries which correspond to the branches of the superior gluteal artery and enter the pelvis via the greater sciatic foramen, above piriformis. They join the internal iliac vein, frequently as a single trunk.

**Inferior gluteal veins**

The inferior gluteal veins are venae comitantes of the inferior gluteal artery. They begin proximally and posterior in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins, and enter the pelvis low in the greater sciatic foramen, joining to form a vessel opening into the distal (lower) part of the internal iliac vein. The inferior gluteal and superficial gluteal veins connect by perforating veins (Doyle 1970) which are analogous to the sural perforating veins. The gluteal veins probably have a venous ‘pumping’ role, and provide collaterals between the femoral and internal iliac veins.

**Obturator vein**

The obturator vein begins in the proximal adductor region and enters the pelvis via the obturator foramen. It runs posteriorly and superiorly on the lateral pelvic wall below the obturator artery and between the ureter and internal iliac artery and ends in the internal iliac vein. It is sometimes replaced by an enlarged pubic vein, which joins the external iliac vein.

**Lateral sacral veins**

The lateral sacral veins accompany the lateral sacral arteries, and are interconnected by a sacral venous plexus.

**Middle rectal vein**

The middle rectal vein begins in the rectal venous plexus and drains the rectum and mesorectum. Variable in size, it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein. The middle rectal vein often receives tributaries from the bladder and either the prostate and seminal vesicle (males) or the posterior aspect of
the vagina (females).

**External iliac vein**

The external iliac vein is the proximal continuation of the femoral vein. It begins posterior to the inguinal ligament, ascends along the pelvic brim and ends anterior to the sacroiliac joint by joining the internal iliac vein to form the common iliac vein. On the right it lies medial to the external iliac artery, gradually inclining behind it as it ascends. On the left it is wholly medial. Disease of the external iliac artery may cause it to adhere closely to the vein at the point where it is in contact, and, particularly on the right side, the walls of the vessels may become fused, making dissection hazardous. The external iliac vein is crossed medially by the ureter and internal iliac artery. In males it is crossed by the vas deferens, in females by the round ligament and ovarian vessels. Psoas major lies laterally, except where the artery intervenes. The vein is usually valveless, but may contain a single valve. Its tributaries are the inferior epigastric, deep circumflex iliac and pubic veins.

**Inferior epigastric vein**

One or two inferior epigastric veins accompany the inferior epigastric artery and drain into the external iliac vein a little above the inguinal ligament.

**Deep circumflex iliac vein**

The deep circumflex vein is formed from venae comitantes of the corresponding artery. It joins the external iliac vein a little above the inferior epigastric vein after crossing anterior to the external iliac artery.

**Pubic vein**

The pubic vein connects the external iliac and obturator veins. It ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery and sometimes replaces the normal obturator vein.

**Lymphatic drainage of the pelvis**

The lymph nodes in the pelvis are grouped around the common, external and internal iliac vessels, and are named accordingly.

**Common iliac nodes**

The common iliac nodes receive the entire lymphatic drainage of the lower limb because they drain both internal and external iliac nodes. They usually lie in medial, lateral and anterior chains around the common iliac artery, the lateral being the main route: one or two lie inferior to the aortic bifurcation and anterior to the fifth lumbar vertebra or sacral promontory. The common iliac nodes connect to the lateral aortic nodes.

**External iliac nodes**

The external iliac nodes usually form three subgroups which are lateral, medial and anterior to the external iliac vessels. The medial nodes are considered the main channel of drainage, collecting lymph from the lower limb via the inguinal nodes, the
deeper layers of the infra-umbilical abdominal wall, the adductor region of the thigh, the glans penis or clitoris, the membranous urethra, prostate, fundus of the bladder, uterine cervix and upper vagina. Their efferents pass to the common iliac nodes.

**Inferior epigastric and circumflex iliac nodes**

The inferior epigastric and circumflex iliac nodes are associated with their similarly named vessels and drain the corresponding areas to the external iliac nodes.

**Internal iliac nodes**

The internal iliac nodes surround the branches of the internal iliac vessels. They receive afferents from most of the pelvic viscera (with the exception of the gonads and the majority of the rectum), the deeper parts of the perineum and the gluteal and posterior femoral muscles, and drain to the common iliac nodes. The individual groups are considered in the description of the viscera. There are frequent connections between the right and left groups particularly when they lie close to the anterior and posterior midlines (Fig. 63.8).
Fig. 63.8 Lymphatic drainage of the female pelvis and urinary bladder.
INNERVATION OF THE PELVIS

The pelvis contains the lumbosacral nerve trunk, the sacral and coccygeal plexuses and the pelvic parts of the sympathetic and parasympathetic systems. Collectively, these nerves carry the somatic and autonomic innervation to the majority of the pelvic visceral organs, the pelvic floor and perineum, the gluteal region and the lower limb.

The ventral rami of the sacral and coccygeal spinal nerves form the sacral and coccygeal plexuses (Fig. 63.9). The upper four sacral ventral rami enter the pelvis by the anterior sacral foramina, the fifth enters between the sacrum and coccyx, and the ventral ramus of the coccygeal nerve curves forwards below the rudimentary transverse process of the first coccygeal segment. The first and second sacral ventral rami are large, the third to fifth diminish progressively, and the coccygeal is the smallest. Each receives a grey ramus communicans from a corresponding sympathetic ganglion. Visceral efferent rami leave the second to fourth sacral rami as the pelvic splanchnic nerves, containing parasympathetic fibres to minute ganglia in the walls of the pelvic viscera.
**Lumbosacral trunk and sacral plexus**

The sacral plexus is formed by the lumbosacral trunk, the first to third sacral ventral rami and part of the fourth sacral ventral ramus (the remainder of the fourth sacral ventral ramus joins the coccygeal plexus).

The lumbar part of the lumbosacral trunk contains part of the fourth and all the fifth lumbar ventral rami; it appears at the medial margin of psoas major, and descends over the pelvic brim anterior to the sacroiliac joint to join the first sacral ramus. The greater part of the second and third sacral rami converge on the inferomedial aspect of the lumbosacral trunk in the greater sciatic foramen to form the sciatic nerve. The ventral and dorsal divisions of the nerves do not separate physically from each other, but their fibres remain separate within the rami; the ventral and dorsal divisions of each contributing root join within the sciatic nerve. The fibres of the dorsal divisions will go on to form the common fibular nerve and the fibres of the ventral division form the tibial nerve. The sciatic nerve occasionally divides into common fibular and tibial nerves inside the pelvis. In these cases the common fibular nerve usually runs through piriformis.

The sacral plexus lies against the posterior pelvic wall anterior to piriformis, posterior to the internal iliac vessels and ureter, and behind the sigmoid colon on the left. The superior gluteal vessels run either between the lumbosacral trunk and first sacral ventral ramus or between the first and second sacral rami, while the inferior gluteal vessels lie between either the first and second or second and third sacral rami (Fig. 63.9).
The sacral plexus is not commonly involved in malignant tumours of the pelvis because it lies behind the relatively dense presacral fascia, which resists all but locally very advanced malignant infiltration. When it occurs, there is intractable pain in the distribution of the branches of the plexus which may be very difficult to treat. The plexus may also be involved in the reticuloses or be affected by plexiform neuromas.

**Branches of the sacral plexus**

The branches of the sacral plexus are:

The course and distribution of most of the branches of the sacral plexus are covered fully on page 1384.

**Pudendal nerve (in the pelvis)**

The pudendal nerve arises from the ventral divisions of the second, third and fourth sacral ventral rami and is formed just above the superior border of the sacrotuberous ligament and the upper fibres of ischiococcygeus. It leaves the pelvis via the greater sciatic foramen between piriformis and ischiococcygeus, enters the gluteal region and crosses the sacrospinous ligament close to its attachment to the ischial spine, where it lies medial to the internal pudendal vessels. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal (Alcock's) canal on the lateral wall of the ischio-anal fossa. In the posterior part of the canal it gives rise to the inferior rectal nerve, the perineal nerve and the dorsal nerve of the penis or clitoris.

**Sacral visceral branches**

Visceral branches, the pelvic splanchnic nerves, arise from the second to fourth sacral ventral rami and innervate the pelvic viscera.

**Sacral muscular branches**
Several muscular branches arise from the fourth sacral ventral ramus to supply the superior surface of levator ani and the upper part of the external anal sphincter. The branches to levator ani enter the superior (pelvic) surface of the muscle whilst the branch to the external anal sphincter (also referred to as the perineal branch of the fourth sacral nerve) reaches the ischio-anal fossa by running either through ischiococcygeus or between ischiococcygeus and iliococcygeus. It supplies the skin between the anus and coccyx via its cutaneous branches.

**Coccygeal plexus**

The coccygeal plexus is formed by a small descending branch from the fourth sacral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curves round the lateral margin of the sacrum below its cornu and pierces ischiococcygeus from below to reach its upper, pelvic surface. Here it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of ischiococcygeus and joins the minute coccygeal ventral ramus which emerges from the sacral hiatus and curves round the lateral coccygeal margin to pierce coccygeus to reach the pelvis. The small trunk that is formed in this way is the coccygeal plexus. Anococcygeal nerves arise from it and form a few fine filaments which pierce the sacrotuberosous ligament to supply the adjacent skin.

**Pelvic part of the sympathetic system**

The pelvic sympathetic trunk lies in the extraperitoneal tissue anterior to the sacrum beneath the presacral fascia (Fig. 63.10). It lies medial or anterior to the anterior sacral foramina and has four or five interconnected ganglia. Above, it is continuous with the lumbar sympathetic trunk. The right and left trunks converge below the lowest ganglia and unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to sacral and coccygeal spinal nerves but there are no white rami communicantes. Medial branches connect across the midline and twigs from the first two ganglia join the inferior hypogastric plexus or the hypogastric ‘nerve’. Other branches form a plexus on the median sacral artery.
Vascular branches

Preganglionic fibres for the vessels supplying the pelvis and lower limb are derived from the lower three thoracic and upper two or three lumbar spinal segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia. Postganglionic fibres pass from these ganglia via grey rami communicantes to the femoral nerve which carries them to the femoral artery and its branches. Some fibres descend through the lumbar ganglia to synapse in the upper two or three sacral ganglia, from which postganglionic axons pass through grey rami communicantes to the roots of the sacral plexus. Those in the pudendal and superior and inferior gluteal nerves accompany the arteries of the same name to the gluteal and perineal tissues; branches may also supply the pelvic lymph nodes. Those joining the tibial nerve are carried to the popliteal artery and distributed via its branches to the leg and foot.

Sympathetic denervation of vessels in the lower limb can be effected by removing or ablating the upper three lumbar ganglia and the intervening parts of the sympathetic trunk, which is used rarely in treating vascular insufficiency of the lower limb.
PERINEUM

MUSCLES AND FASCIAE OF THE PERINEUM

The perineum is an approximately diamond-shaped region which lies below the pelvic floor, between the inner aspects of the thighs and anterior to the sacrum and coccyx. It is usually described as if from the position of an individual lying supine with the hip joints in abduction and partial flexion. The surface projection of the perineum and the form of the skin covering it varies considerably depending on the position of the thighs whereas the deep tissues themselves occupy relatively fixed positions. The perineum is bounded anteriorly by the pubic symphysis and its arcuate ligament, posteriorly by the coccyx, anterolaterally by the ischiopubic rami and the ischial tuberosities, and posterolaterally by the sacrotuberous ligaments. The deep limit of the perineum is the inferior surface of the pelvic diaphragm and its superficial limit is the skin which is continuous with that over the medial aspect of the thighs and the lower abdominal wall. An arbitrary line joining the ischial tuberosities (the interischial line) divides the perineum into an anterior urogenital triangle and a posterior anal triangle. The urogenital triangle faces downwards and forwards, whereas the anal triangle faces downwards and backwards.

The male urogenital triangle contains the bulb and attachments of the penis (Fig. 63.11) (Ch. 76) and the female urogenital triangle contains the mons pubis, the labia majora, the labia minora, the clitoris and the vaginal and urethral orifices (Ch. 77).
Muscles and fasciae of the male perineum. On the left side the skin and superficial fascia of the perineum only have been removed. The posterior scrotal (perineal) artery has been shown as it runs forward into the scrotal tissues. On the right side, the corpora cavernosa and corpus spongiosum and their associated muscles, the superficial perineal muscles and perineal membrane have been removed to reveal the underlying deep muscles and arteries of the perineum. All veins and nerves have been omitted for clarity.

Anal triangle

The structure of the anal triangle is similar in males and females, the main difference reflecting the wider transverse dimension of the triangle in females as a result of the larger size of the pelvic outlet. The anal triangle contains the anal canal and its sphincters, and the ischio-anal fossa and its contained nerves and vessels. It is lined by superficial and deep fascia.

Superficial fascia of the anal triangle

The superficial fascia of the region is thin and is continuous with the superficial/subcutaneous fascia of the skin of the perineum, thighs and buttocks (see p. 1095).

Deep fascia of anal triangle

The deep fascia lines the inferior surface of levator ani and is continuous at its lateral origin with the fascia over obturator internus below the attachment of levator ani. It lines the deep portion of the ischio-anal fossa and its lateral walls.

Ischio-anal fossa

The ischio-anal fossa is an approximately horse-shoe shaped region filling the majority of the anal triangle; although often referred to as a space, it is filled with loose adipose tissue and occasional blood vessels. The 'arms' of the horseshoe are triangular in cross section because levator ani slopes downwards towards the anorectal junction (see Fig. 67.43). The anal canal and its sphincters lie in the centre of the horseshoe. Above them the deep medial limit of the fossa is formed by the deep fascia over levator ani. The outer boundary of the fossa is formed anterolaterally by the deep fascia over obturator internus deeply and the periosteum of the ischial tuberosities more superficially. Posterolaterally, the outer boundary is formed by the lower border of gluteus maximus and the sacrotuberous ligament. Anteriorly, the
superficial boundary of the fossa is formed by the posterior aspect of the transverse perineal muscles and the deep perineal pouch. Deep to this there is no fascial boundary between the fossa and the tissues deep to the perineal membrane as far anteriorly as the posterior surface of the pubis below the attachment of levator ani. Posteriorly, the fossa contains the attachment of the external anal sphincter to the tip of the coccyx: above and below this, the adipose tissue of the fossa is uninterrupted across the midline. These continuations of the ischio-anal fossa mean that infections, tumours and fluid collections within may not only enlarge relatively freely to the side of the anal canal, but may also spread with little resistance to the opposite side and deep to the perineal membrane. The internal pudendal vessels and accompanying nerves lie in the lateral wall of the ischio-anal fossa, enclosed in fascia forming the pudendal canal. The inferior rectal vessels and nerves cross the fossa from the pudendal canal and often branch within it.

The ischio-anal fossa is an important surgical plane during resections of the anal canal and anorectal junction for malignancy. It provides an easy, relatively bloodless, plane of dissection which encompasses all of the muscular structures of the anal canal and leads to the inferior surface of levator ani through which the dissection is carried.

*External anal sphincter*

The external anal sphincter is an oval tube of striated muscle which surrounds the lowest part of the anal canal. The uppermost (deepest) fibres blend with the lowest fibres of puborectalis; the two are seen to be continuous on endoanal ultrasound and magnetic resonance imaging. Anteriorly, some of these upper fibres decussate into the superficial transverse perineal muscles. Posteriorly, some fibres are attached to the anococygeal raphe. The majority of the middle fibres of the external anal sphincter surround the lower part of the internal sphincter and are attached anteriorly to the perineal body and posteriorly to the coccyx via the anococcygeal ligament. Some fibres from each side of the sphincter decussate in these areas to form a sort of commissure in the anterior and posterior midline. The anterior and posterior attachments of the external anal sphincter give the muscular tube an oval profile lying anteroposteriorly. The lower fibres lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium only by submucosa.

*Anococcygeal ligament*

The anococcygeal ligament is a layered musculotendinous structure running between the middle portion of the external anal sphincter and the coccyx. The lowest portion of the presacral fascia lies above the deep part of the ligament and the most posterior fibres of the raphe of iliococcygeus lie between the two: these three structures together are sometimes referred to as the postanal plate. Division of the anococcygeal raphe may cause descent of the anal canal and a lowering of the posterior part of the anal triangle, but does not demonstrably interfere with the process of defecation.

*Urogenital triangle*

The urogenital triangle is bounded posteriorly by the inter-ischial line which usually overlies the posterior border of the transverse perineal muscles. Anteriorly and laterally it is bounded deeply by the symphysis pubis and ischiopubic rami. In males, the urogenital triangle extends superficially to encompass the scrotum and the root of
the penis. In females, it extends to the lower limit of the labia and mons pubis. The urogenital triangle is divided into two parts by a strong perineal membrane: the deep perineal space lies above the membrane and the superficial perineal space lies below it.

The female urogenital triangle includes muscles, fasciae and spaces similar to those in the male. There are some differences in size and disposition caused by the presence of the vagina and female external genitalia.

**Deep perineal pouch (space)**

The deep perineal pouch was long regarded as an anatomical region between the urogenital diaphragm and the perineal membrane containing the urethra and urethral sphincter. However, the urogenital diaphragm does not exist and the urethral sphincter, previously thought to be the principal content of the deep perineal space (where it was described as surrounding the urethra), is now recognized to be contained within the urethra. The deep perineal pouch is bounded deeply by the endopelvic fascia of the pelvic floor and superficially by the perineal membrane. Between these two fascial layers lie the deep transverse perinei, superficial to the urethral sphincter mechanism and pubourethralis, and in females superficial to the compressor urethrae and sphincter urethrovaginalis. These muscles do not form a true diaphragmatic sheet as such because fibres from several parts extend through the visceral outlet in the pelvic floor into the lower reaches of the pelvic cavity.

**Perineal membrane (previously the inferior fascia of the urogenital diaphragm)**

The perineal membrane is a triangular membrane which stretches almost horizontally across the deep perineal pouch. It is attached laterally to the periosteum of the ischiopubic rami and its apex is attached to the arcuate ligament of the pubis. It is particularly thick in this area and is here referred to as the transverse perineal ligament. The posterior border is fused with the deep part of the perineal body and is continuous with the fascia over the deep transverse perinei.

In the male, the perineal membrane is crossed by the urethra, 2–3 cm behind the inferior border of the symphysis pubis; the vessels and nerves to the bulb of the penis; the ducts of the bulbourethral glands, posterolateral to the urethral orifice; the deep dorsal vessels and dorsal nerves of the penis, behind the pubic arch in the midline; and the posterior scrotal vessels and nerves, anterior to the transverse perinei.

In the female, the perineal membrane is less well defined than in the male. It is divided almost into two halves by the vagina and urethra such that it forms a triangle on each side of these structures; the pubourethral ligament (the female equivalent of the transverse perineal ligament in males) links the two sides anteriorly behind the pubic arch. It is crossed by the urethra, 2–3 cm behind the inferior border of the symphysis pubis; the vagina, centrally; the ducts of Bartholin's glands, posterolateral to the urethral orifice; the deep dorsal vessels and dorsal nerves of the clitoris, behind the pubic arch in the midline; the posterior labial vessels and nerves, anterior to the transverse perinei.

**Deep transverse perinei**

The deep transverse perinei form an incomplete sheet of muscle extending across the
deep perineal pouch from the medial aspects of the ischiopubic rami. Posteriorly the sheet is attached to the perineal body where its fibres decussate with those of the opposite side. Anteriorly, the muscles are deficient and the visceral structures pass across the endopelvic fascia and the perineal membrane. Some fibres pass to the deep part of the external anal sphincter posteriorly and sphincter urethrae anteriorly. Together with the superficial transverse perinei, the muscles act to tether the perineal body in the median plane and may help to support the visceral canals which pass through them. They are supplied by the perineal branches of the pudendal vessels and nerves.

Urethral sphincter mechanism

The urethral sphincter mechanism consists of the intrinsic striated and smooth muscle of the urethra and the puboperinealis (pubourethralis) component of levator ani which surrounds the urethra at the point of maximum concentration of those muscles. It surrounds the membranous urethra in the male and the middle and lower thirds of the urethra in the female. In the male, fibres also reach up to the lowest part of the neck of the bladder and, between the two, lie on the surface of the prostate. The bulk of the fibres surround the membranous urethra and some fibres are attached to the inner surface of the ischiopubic ramus. In the female, the sphincter mechanism surrounds more than the middle third of the urethra. It blends above with the smooth muscle of the bladder neck and below with the smooth muscle of the lower urethra and vagina.

Actions

The urethral sphincter mechanism compresses the urethra, particularly when the bladder contains fluid. Its location around the region of highest urethral closing pressure suggests that it plays an important role in the continence of urine. Like bulbospongiosus, it is relaxed during micturition, but it contracts to expel final drops of urine, or of semen in the male, from the bulbar urethra. It may be stimulated via a vaginal tampon electrode, as has been used in the treatment of stress incontinence of urine in females.

Innervation

The urethral sphincter mechanism extends from the perineum through the urogenital hiatus into the pelvic cavity. It probably receives innervation via the perineal branch of the pudendal nerve from below and direct branches from the sacral plexus and the pelvic splanchnic nerves from above (Wendell-Smith & Wilson 1991). All these nerves originate in the second, third and fourth sacral spinal segments.

Compressor urethrae

Compressor urethrae exists in females and arises from the ischiopubic rami of each side by a small tendon. Fibres pass anteriorly to meet their contralateral counterparts in a flat band which lies anterior to the urethra, below sphincter urethrae (Fig. 63.12). A variable number of fibres from the same origin fan medially to reach the lower walls of the vagina, and may rarely reach as far posteriorly as the perineal body.
Sphincter urethrovaginalis

Sphincter urethrovaginalis exists in females and arises from the perineal body. Fibres pass forwards on either side of the vagina and urethra to meet their contralateral counterparts in a flat band, anterior to the urethra, below compressor urethrae.

Actions

The direction of the fibres of compressor urethrae and sphincter urethrovaginalis suggests that they produce elongation as well as compression of the membranous urethra and thus aid continence in females.

Superficial and deep perineal fasciae

Superficial perineal fascia

The tissue commonly referred to as the superficial fascia of the perineum (Colles' fascia) forms a clear, surgically recognizable plane beneath the skin of the anterior perineum. It is firmly attached posteriorly to the fascia over the superficial transverse perinei and the posterior limit of the perineal membrane. Laterally, it is attached to the margins of the ischiopubic rami as far back as the ischial tuberosities. From here it runs more superficially to the skin of the urogenital triangle, lining the skin of the external genitalia; in the male it is also continuous with the fascial layer in the skin of the scrotum which contains the dartos muscle. In females, the fascia follows the same limits but is much less extensive in the labia majora. This layer runs anteriorly and superiorly into the skin of the lower abdominal wall where it is continuous with the membranous fascia (Scarpa's fascia). These tissue layers are referred to in English as a 'superficial fascia' but this is really a misnomer since they are correctly referred to as
the membranous layer of the subcutaneous tissue (the tela subcutanea).

Deep perineal fascia (investing fascia of the superficial perineal muscles)

The tissue commonly referred to as the deep perineal fascia is a layer of fascia overlying the superficial muscles of the perineum (bulbospongiosus, ischiocavernosus, superficial transverse perinei). It is in effect the investing fascia of the superficial perineal muscles and as such is firmly attached to the borders of the muscles at attachments to the ischiopubic rami, posterior margin of the perineal membrane and perineal body. In front it fuses with the suspensory ligament of the penis or clitoris and the fasciae of external oblique and the rectus sheath.

Superficial and subcutaneous perineal pouches

Subcutaneous perineal pouch

The subcutaneous perineal pouch lies between the deep perineal fascia and the superficial perineal fascia. Under normal circumstances these two layers are only separated by relatively thin subcutaneous connective tissue and the skin of the anterior perineum and genitals is relatively mobile over the deeper structures. This pouch is, however, capable of expanding considerably in the presence of fluid accumulation; blood, urine or fluid collecting in the subcutaneous pouch due to trauma or surgery on the urogenital triangle will spread throughout the tissues of the triangle including the scrotum or labia majora, but cannot pass posteriorly into the anal triangle or laterally into the medial thigh due to the firm tethering of the posterior attachments of the subcutaneous fascia. Since the superficial perineal fascia is in continuity with the fascia of the anterior abdominal wall, fluid, blood or pus may also track freely between the subcutaneous tissues of the anterior abdominal wall and the subcutaneous perineal pouch (e.g. post surgical haematomas of the abdominal wall readily cause discolouration of the perineal and genital skin).

Superficial perineal pouch

The superficial perineal pouch lies below the perineal membrane and is limited superficially by the deep perineal fascia (investing fascia of the superficial perineal muscles) (Fig. 63.13). It contains the corpora cavernosa and corpus spongiosum, ischiocavernosus, bulbospongiosus and the superficial transverse perinei, and branches of the pudendal vessels and nerves. In the female, it is crossed by the urethra and vagina and contains the clitoris. In the male, it contains the urethra as it runs in the root of the penis. It is a fully confined space; injuries to the contents of the space (such as bleeding into the urethra in the penile root) do not communicate with the deep or subcutaneous pouches unless the fascial coverings are also lacerated or breached.

Perineal body

The perineal body is a poorly defined aggregation of fibromuscular tissue located in the midline at the junction between the anal and urogenital triangles. It is attached to many structures in both the deep and superficial urogenital spaces. Posteriorly, it merges with fibres from the middle part of the external anal sphincter and the conjoint longitudinal coat. Superiorly, it is continuous with the rectoprostatic or rectovaginal septum, including fibres from levator ani (puborectalis or pubovaginalis). Anteriorly, it
receives a contribution from the deep transverse perinei, the superficial transverse perinei and bulbospongiosus (Fig. 63.4). The perineal body is continuous with the perineal membrane and the superficial perineal fascia. Since the superficial perineal fascia runs forward into the skin of the perineum, the perineal body is tethered to the central perineal skin, which is often puckered over it. In males, this is continuous with the perineal raphe in the skin of the scrotum. In females, the perineal body lies directly posterior to, and is attached to, the posterior commissure of the labia majora and the introitus of the vagina.

The anus can be surgically detached from the perineal body without any clinical consequences. However, spontaneous lacerations of the body sustained during childbirth are often associated with damage to the anterior fibres of the external anal sphincter. The deliberate division of the perineal body to facilitate delivery (episiotomy) is angled laterally to avoid such injuries. The perineal body is often used for the positioning of radiological markers used to determine the amount the perineum descends during straining in order to assess pelvic floor dysfunction.

**Superficial transverse perinei**

The superficial transverse perinei are narrow strips of muscle which run more or less transversely across the superficial perineal space anterior to the anus. The muscles are occasionally small and rarely absent. On each side the muscle is attached to the medial and anterior aspects of the ischial tuberosity. Medially, the fibres mostly run into the perineal body although some may also pass into the ipsilateral bulbospongiosus or external anal sphincter.

**Bulbospongiosus**

Bulbospongiosus differs between the sexes. In the male, it lies in the midline, anterior to the perineal body. It consists of two symmetrical parts united by a median fibrous raphe. The fibres attach to the perineal body, in which they decussate, and to the transverse superficial perinei and the external anal sphincter; they diverge like the sides of a feather from the median raphe. A thin layer of posterior fibres joins the posterior portion of the perineal membrane. The majority of the middle fibres encircle the bulb of the penis and adjacent corpus spongiosum and attach to an aponeurosis on the dorsal surfaces. The anterior fibres spread out over the sides of the corpora cavernosa, ending partly in them, anterior to ischiocavernosus, and partly in a tendinous expansion which covers the dorsal vessels of the penis. In the female, bulbospongiosus also attaches to the perineal body, but the muscle on each side is separate and covers the superficial parts of the vestibular bulbs and greater vestibular glands. Fibres run anteriorly on either side of the vagina to attach to the corpora cavernosa clitoridis, and a few fibres cross over the dorsum of the body of the clitoris.

**Actions**

Bulbospongiosus helps to empty the urethra of urine after the bladder has emptied. In the male, it may assist in the final stage of erection as the middle fibres compress the erectile tissue of the bulb and the anterior fibres contribute by compressing the deep dorsal vein of the penis. It contracts six or seven times during ejaculation, assisting in the expulsion of semen. In the female, bulbospongiosus acts to constrict the vaginal orifice and express the secretions of the greater vestibular glands. Anterior fibres contribute to erection of the clitoris by compressing its deep dorsal vein.
**Ischiocavernosus**

In the male, ischiocavernosus covers the crus penis. It is attached by tendinous and muscular fibres to the medial aspect of the ischial tuberosity behind, and to the ischial ramus on both sides of the crus. These fibres end in an aponeurosis which is attached to the sides and under surface of the crus penis. In the female, ischiocavernosus is related to a smaller crus clitoris and has a much smaller attachment to the ischiopubic ramus, but is otherwise similar to the corresponding muscle in the male (Figs 63.14, 63.15).

![Muscles and fasciae of the female perineum – coronal T2-weighted MRI.](image)

*Fig. 63.15  Muscles and fasciae of the female perineum – coronal T2-weighted MRI. (By courtesy of Dr J Lee and Ms K Wimpey, Chelsea and Westminster Hospital, London.)*

**Action**

Ischiocavernosus compresses the crus penis in males and may help to maintain penile erection. The muscles form a triangle on each side of the midline with bulbospongious medially and the superficial transverse perinei posteriorly, attached to the perineal membrane: when contracted, the two ischiocavernosi act together to stabilize the erect penis. In the female, ischiocavernosus may help to promote clitoral erection.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE PERINEUM

Arteries of the perineum

Internal pudendal artery (in the perineum)

The internal pudendal artery enters the perineum around the posterior aspect of the ischial spine and runs on the lateral wall of the ischio-anal fossa in the pudendal (Alcock's) canal with the pudendal veins and the pudendal nerve. The canal is formed by the connective tissue binding the vessels and nerve to the perineal surface of the obturator internus fascia and lies about 4 cm above the lower limit of the ischial tuberosity. As the artery approaches the margin of the ischial ramus, it proceeds above or below the perineal membrane, along the medial margin of the inferior pubic ramus and ends behind the inferior pubic ligament.

In the male, the internal pudendal artery distal to the perineal artery gives a branch to the bulb of the penis before it divides into the deep (cavernosal) and dorsal arteries of the penis (Fig. 63.11). Given its distribution, the internal pudendal artery distal to its perineal branch has been named the artery of the penis. The artery to the bulb supplies the corpus spongiosum and the deep artery to the penis supplies the corpus cavernosa on each side. The dorsal artery runs on the dorsal aspect of the penis, and supplies circumflex branches to the corpora cavernosa and corpus spongiosum which end by anastomosing in the coronal sulcus and supplying the glans penis and its overlying skin.

In the female, the artery to the bulb is distributed to the erectile tissue of the vestibular bulb and vagina. The cavernosal artery is much smaller and supplies the corpora cavernosa of the clitoris; the dorsal artery supplies the glans and prepuce of the clitoris (Fig. 63.11).

Branches of the internal pudendal artery are sometimes derived from an accessory pudendal artery, which is usually a branch of the pudendal artery before its exit from the pelvis; effectively the artery is double before it leaves the pelvis.

Inferior rectal artery

The inferior rectal artery arises just after the internal pudendal artery enters the canal on the lateral wall of the ischio-anal fossa and runs anteromedially through the adipose tissue of the ischio-anal fossa to reach the deep portion of the external anal sphincter. It often branches before reaching the sphincter. During dissections of the anal canal, particularly during perineal excisions of the anorectum, the inferior rectal vessels are encountered in the ischio-anal fossa and must be secured before division or they tend to retract.
laterally to the canal, where they can cause troublesome bleeding.

**Perineal artery**

The perineal artery is a branch of the internal pudendal artery near the anterior end of the pudendal canal, and runs through the perineal membrane. In the male, it approaches the scrotum in the superficial perineal space, between bulbospongiosus and ischiocavernosus. A small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with the contralateral artery and with the posterior scrotal and inferior rectal arteries. It supplies the transverse perinei, the perineal body and the posterior attachment of the bulb of the penis. The posterior scrotal arteries are usually terminal branches of the perineal artery but may also arise from its transverse branch. They are distributed to the scrotal skin and dartos muscle in the male and supply the perineal muscles. In the female, the perineal artery runs an almost identical course to that in the male, and gives off similar branches; the posterior scrotal arteries are replaced by posterior labial arteries.

**Veins of the perineum: internal pudendal veins**

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel ending in the internal iliac vein. The perineal tributaries receive veins from the penile bulb and the scrotum (males) or clitoris and labia (females) and the inferior rectal veins join towards the posterior end of the pudendal canal.

**Lymphatic drainage of the perineum**

The lymphatics from the skin of the penis and scrotum (male) or skin of the clitoris and labia (female) drain together with lymphatics from the perineal skin to the superficial inguinal nodes and thence to the deep inguinal nodes. The glans, corpora cavernosa and corpus spongiosum of the penis or clitoris drain directly to the deep inguinal nodes.
INNERVATION OF THE PERINEUM: PUDENDAL NERVE (IN THE PERINEUM)

The pudendal nerve gives rise to the inferior rectal and perineal nerves and the dorsal nerves of the penis or clitoris.

The pudendal nerve occupies a very constant position over the ischial spine and is readily found. It may be ‘blocked’ by infiltration with a local anaesthetic applied via a needle passed through the lateral wall of the vagina to numb the perineal and anal skin. It may also be palpated over the ischial spine through the lateral wall of the rectum and motor terminal latencies measured.

**Inferior rectal nerve**

The inferior rectal nerve runs through the medial wall of the pudendal canal with the inferior rectal vessels. It crosses the ischio-anal fossa to supply the external anal sphincter, the lining of the lower part of the anal canal, and the circumanal skin. It frequently breaks into terminal branches just before reaching the lateral border of the sphincter. Its cutaneous branches distributed around the anus overlap the cutaneous branches of the perineal branch of the posterior femoral cutaneous nerve and of the scrotal or labial nerves. The inferior rectal nerve occasionally arises directly from the sacral plexus and crosses the sacrospinous ligament or reconnects with the pudendal nerve. In females, the inferior rectal nerve may supply sensory branches to the lower part of the vagina.

**Perineal nerve**

The perineal nerve is the inferior and larger terminal branch of the pudendal nerve in the pudendal canal. It runs forwards below the internal pudendal artery and accompanies the perineal artery, dividing into posterior scrotal or labial and muscular branches. The posterior scrotal or labial nerves are usually double and have medial and lateral branches which run over the perineal membrane and pass forwards in the lateral part of the urogenital triangle with the scrotal or labial branches of the perineal artery. They supply the skin of the scrotum or labia majora, overlapping the distribution of the perineal branch of the posterior femoral cutaneous and inferior rectal nerves. In females, the posterior labial branches also supply sensory fibres to the skin of the lower vagina.

Muscular branches arise directly from the pudendal nerve to supply the superficial transverse perinei, bulbospongiosus, ischiocavernosus, deep transverse perinei, sphincter urethrae and the anterior parts of the external anal sphincter and levator ani. In males, a nerve to the bulb of the urethra leaves the nerve to the bulbospongiosus, pierces this muscle to supply the corpus spongiosum penis and ends in the urethral mucosa.
Dorsal nerve of the penis or clitoris

The dorsal nerve of the penis or clitoris runs anteriorly above the internal pudendal artery along the ischiopubic ramus deep to the perineal membrane. It supplies the corpus cavernosum and accompanies the dorsal artery of the penis or clitoris between the layers of the suspensory ligament. In males, the dorsal nerve of the penis runs on the dorsum of the penis to end in the glans. In females the dorsal nerve of the clitoris is very small.
REFERENCES

CHAPTER 64 – Peritoneum and peritoneal cavity

The peritoneum is the largest serous membrane in the body, and its arrangements are complex. In males it forms a closed sac, but in females it is open at the lateral ends of the uterine tubes. It consists of a single layer of flat mesothelial cells lying on a layer of loose connective tissue. The mesothelium usually forms a continuous surface, but in some areas may be fenestrated. Neighbouring cells are joined by junctional complexes, but probably permit the passage of macrophages. The submesothelial connective tissue may also contain macrophages, lymphocytes and adipocytes (in some regions). Mesothelial cells may transform into fibroblasts, which may play an important role in the formation of peritoneal adhesions after surgery or inflammation of the peritoneum.

The peritoneal cavity is a potential space between the parietal peritoneum, which lines the abdominal wall, and infoldings of visceral peritoneum, which suspend the abdominal viscera within the cavity. It contains a small amount of serous fluid, but is otherwise empty. The fluid lubricates the visceral peritoneum and allows the mobile viscera to glide freely on the abdominal wall and each other within the limits dictated by their attachments. It contains water, proteins, electrolytes and solutes derived from interstitial fluid in the adjacent tissues and from the plasma in the local blood vessels. It normally contains a few cells, including desquamated mesothelium, nomadic peritoneal macrophages, mast cells, fibroblasts, lymphocytes and other leukocytes. Some cells, particularly macrophages, migrate freely between the peritoneal cavity and the surrounding connective tissue. Lymphocytes provide both cellular and humoral immunological defence mechanisms within the peritoneal cavity. The intraperitoneal fluid is directed by gravity to dependent sites within the peritoneal cavity, and also flows in a cephalad direction as a consequence of the negative upper intra-abdominal pressures which are generated by respiration.

The peritoneal cavity never contains gas in normal circumstances, although the amount of fluid may be increased in inflammatory conditions of the viscera. In females blood or fluid may occasionally escape from the uterine tubes into the pelvic peritoneal cavity during menstruation.

Extraperitoneal connective tissue separates the parietal peritoneum from the muscular layers of the abdominal walls. The parietal peritoneum covering the anterior abdominal wall and pelvic walls is generally attached only loosely by this tissue, an arrangement which allows for considerable alteration in the size of the bladder and rectum. The extraperitoneal tissue on the inferior surface of the diaphragm and behind the linea alba is denser and more firmly adherent. The extraperitoneal tissue frequently contains large amounts of fat over the posterior abdominal wall, especially in obese males. The visceral peritoneum is firmly adherent to the underlying tissues and cannot be easily detached. Its connective tissue layer is often continuous with the fibrous matrix of the wall of the underlying viscera and rarely contains much loose connective or adipose tissue. The visceral peritoneum is often considered as part of the underlying viscus for clinical and pathological purposes such as the staging of carcinoma.

GENERAL ARRANGEMENT OF THE PERITONEUM

In utero, the alimentary tract develops as a single tube suspended in the coelomic
cavity by ventral and dorsal mesenteries (see Ch. 73). Ultimately, the ventral mesentery is largely resorbed, although some parts persist in the upper abdomen and form structures such as the falciform ligament. The mesenteries of the intestines in the adult are the remnants of the dorsal mesentery. The migration and subsequent fixation of parts of the gastrointestinal tract produce the so-called ‘retroperitoneal’ segments of bowel (duodenum, ascending colon, descending colon, and rectum), and four separate intraperitoneal bowel loops suspended by mesenteries of variable lengths. These are all covered by visceral peritoneum which is continuous with the parietal peritoneum covering the posterior abdominal wall. The first intraperitoneal loop is formed by the intraperitoneal oesophagus, the stomach and first part of the duodenum. The second loop is made up of the duodenojejunal junction, jejunum, ileum and occasionally the caecum and proximal ascending colon. The third loop contains the transverse colon and the final loop contains the sigmoid colon and occasionally the distal descending colon.

Where the visceral peritoneum encloses or suspends organs within the peritoneal cavity, the peritoneum and related connective tissues are known as the peritoneal ligaments, omenta or mesenteries. All but the greater omentum are composed of two layers of visceral peritoneum separated by variable amounts of connective tissue. The greater omentum is folded back on itself and is therefore made up of four layers of closely applied visceral peritoneum, which are separated by variable amounts of adipose tissue. The mesenteries attach their respective viscera to the posterior abdominal wall: the attachment is referred to as the mesenteric root, and the peritoneum of the mesentery is continuous with that of the posterior abdominal wall in this area (Fig. 64.1).
Fig. 64.1 The posterior abdominal wall, showing the lines of peritoneal reflection, after removal of the liver, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile (retroperitoneal) organs are seen shining through the posterior parietal peritoneum. Note: the ascending and descending colon, duodenum, kidneys, suprarenals, pancreas and inferior vena cava. Line W–W represents the plane of Fig. 64.2. Line X–X represents the plane of Fig. 64.3. Line Y–Y represents the plane of Fig. 64.4. Line A–A represents the plane of Fig. 64.5A. Line B–B represents the plane of Fig. 64.5B. Line C–C represents the plane of Fig. 64.5C.

Although they are described as intraperitoneal, strictly speaking the suspended organs do not lie within the peritoneal cavity because they are covered by visceral peritoneum. They are continuous with the extraperitoneal tissues, including the retroperitoneum, via subperitoneal tissue lying between the folds of visceral peritoneum. The loose areolar connective tissues of the extraperitoneal and subperitoneal tissues are sometimes conceptualized as ‘spaces’ because fluid or blood collects relatively easily within them. The subperitoneal tissues contain the neurovascular bundles and lymphatic channels which supply the suspended organs. In obese individuals, extensive adipose tissue within the mesenteries and omenta may obscure the neurovascular bundles. In contrast, in the very young, the elderly or the malnourished, the mesentery may contain very little adipose tissue and the neurovascular bundles are usually obvious.

**PERITONEUM OF THE UPPER ABDOMEN**

The abdominal oesophagus, stomach, liver and spleen all lie within a double fold of visceral peritoneum which runs from the posterior to the anterior abdominal wall. This fold has no recognized name, but has been referred to as the mesogastrium by Coakley & Hricak 1999 because it is derived from the fetal mesogastrium. It has a complex attachment to the wall of the abdominal cavity and gives rise to the falciform ligament, coronary ligaments, lesser omentum (gastrohepatic and hepatoduodenal ligaments), greater omentum (including gastrocolic ligament), gastroplenic ligament, splenorenal ligament, and phrenicocolic ligament (Figs 64.2, 64.3, 64.4).
Fig. 64.2 Sagittal section through the abdomen to the right of the epiploic foramen along one line of W–W in Fig. 64.1.
Fig. 64.3. Section through the upper part of the abdominal cavity, along the line X–X in Fig. 64.1. The boundaries of the epiploic foramen are shown and a small recess of the lesser sac is displayed in front of the head of the pancreas. Note that the transverse colon and its mesocolon are adherent to the posterior two layers of the greater omentum.
The falciform ligament

The falciform ligament is a thin anteroposterior peritoneal fold which connects the liver to the posterior aspect of the anterior abdominal wall just to the right of the midline. It extends inferiorly to the level of the umbilicus, and is widest between the liver and umbilicus. The ligament narrows superiorly as the distance between the liver and anterior abdominal wall reduces and narrows to just a centimetre or so in height over the superior surface of the liver. Its two peritoneal layers divide to enclose the liver and are continuous with the visceral peritoneum that is adherent to the surface of the liver. Superiorly, they are reflected onto the inferior surface of the diaphragm and are continuous with the parietal peritoneum over the right dome. At the posterior limit, or
The peritoneal connections of the liver

The liver is almost completely covered in visceral peritoneum, and only the 'bare area' is in direct contact with the right dome of the diaphragm. Peritoneal folds, the ligaments of the liver, run from the liver to the surrounding viscera and to the abdominal wall and diaphragm (Fig. 64.5); they are described in detail in Chapter 68.
The coronary ligament is formed by the reflection of the peritoneum from the diaphragm onto the posterior surfaces of the right lobe of the liver. Between the two layers of this ligament, a large area of liver, the bare area, is devoid of peritoneal covering. At this point the liver is attached to the diaphragm by areolar tissue and is in continuity inferiorly with the uppermost part of the anterior pararenal space. The layers of the coronary ligament are continuous on the right with the right triangular ligament.

The upper layer of the coronary ligament is continuous superiorly with the peritoneum over the inferior surface of the diaphragm and inferiorly with the peritoneum over the right and superior surfaces of the liver. At the lower margin of the bare area the lower
layer of the coronary ligament becomes continuous inferiorly with the peritoneum of the posterior abdominal wall over the right suprarenal gland and upper pole of the right kidney, and superiorly with the peritoneum over the inferior surface of the liver.

The left triangular ligament is a double layer of peritoneum which extends over the superior border of the left lobe of the liver to a variable length. Medially, its anterior leaf is continuous with the left layer of the falciform ligament. The posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. Intraoperative division of the left triangular ligament permits mobilization of the left lobe of the liver in order to expose the abdominal oesophagus and crura of the diaphragm.

The right triangular ligament is a short V-shaped fold formed by the approximation of the two layers of the coronary ligament at its right lateral end, and is continuous with the peritoneum of the right posterolateral abdominal wall. The coronary ligament is reflected inferiorly and is directly continuous with the peritoneum over the upper pole of the right kidney. This fold is sometimes referred to as the hepatorenal ligament. The recess formed between the peritoneum of the inferior surface of the liver, the hepatorenal ligament and the peritoneum over the right kidney is known as the hepatorenal pouch (of Morison). In the supine position this is the most dependent part of the peritoneal cavity in the upper abdomen, and is a common site of pathological fluid accumulation.

The peritoneum is reflected inferolaterally from the posterior layer of the left triangular ligament onto the posterior abdominal wall above the oesophageal opening of the diaphragm. It lines the inferior surface of the left dome of the diaphragm and continues backwards onto the posterior abdominal wall. Inferiorly, it is reflected behind the spleen onto the most lateral part of the mesentery of the transverse colon and the splenic flexure. It continues down lateral to the descending colon into the pelvis, and forms the left paracolic ‘gutter’. Medially, the peritoneum covering the left upper posterior abdominal wall is reflected anteriorly to form the left layer of the upper end of the lesser omentum, the peritoneum over the left aspect of the abdominal oesophagus and the left layer of the splenorenal ligament.

From the inferior layer of the coronary ligament the peritoneum descends over the anterior surface of the right kidney to the front of the first part of the duodenum and hepatic flexure of the colon. Medially it passes in front of a short segment of the inferior vena cava between the duodenum and liver, forming as it does so the posterior wall of the epiploic foramen. This narrow strip broadens out as the peritoneum continues across the midline onto the posterior wall of the lesser sac.

The peritoneum lines the posterior abdominal wall over the diaphragmatic crura, the upper abdominal aorta, the coeliac axis, nodes and plexus and the upper border of the pancreas. Inferiorly, below the liver, it continues down on the posterior abdominal wall to the right of the ascending colon, forming the right paracolic ‘gutter’ between the anterolateral abdominal wall and colon.

The lesser omentum

The lesser omentum is formed of two layers of peritoneum separated by a variable
amount of connective tissue and is derived from the ventral mesogastrium. It runs from the inferior visceral surface of the liver to the abdominal oesophagus, stomach, pylorus and first part of the duodenum. Superiorly, its attachment to the inferior surface of the liver forms an L-shape. The vertical component of the L is formed by the fissure for the ligamentum venosum. Inferiorly, the attachment turns and runs horizontally to complete the L in the portal fissure. The vertical and horizontal components of the lesser omentum run between the liver and the stomach and duodenum and are known as the gastrohepatic and hepatoduodenal ligaments, respectively. At the lesser curvature of the stomach, the layers of the lesser omentum split to enclose the stomach and are continuous with the visceral peritoneum covering the anterior and posterior surfaces of the stomach. The anterior layer of the lesser omentum descends from the fissure for the ligamentum venosum onto the anterior surface of the abdominal oesophagus, stomach and duodenum. The posterior layer descends from the posterior part of the fissure for the ligamentum venosum and runs onto the posterior surface of the stomach and pylorus. The lesser omentum forms the anterior surface of the lesser sac. The gastrohepatic ligament contains the right and left gastric vessels, branches of the vagus nerves, and gastrohepatic lymph nodes between its two layers near their attachment to the stomach. The right lateral border of the lesser omentum is thickened and extends from the junction between the first and second parts of the duodenum to the porta hepatis. This border is free and forms the anterior wall of the epiploic foramen. It contains the portal vein, common bile duct, hepatic artery, portocaval lymph nodes and lymphatics and the hepatic plexus of nerves ensheathed in a perivascular fibrous capsule. Occasionally the free margin extends to the right of the epiploic foramen, runs to the gallbladder and is referred to as the cystoduodenal ligament.

The left border of the lesser omentum is short and runs over the inferior surface of the diaphragm between the liver and medial aspect of the abdominal oesophagus. The lesser omentum is thinner on the left and may be fenestrated or incomplete: the variations in thickness are dependent upon the amount of connective tissue, especially fat.

The greater omentum

The greater omentum is the largest peritoneal fold and hangs inferiorly from the greater curvature of the stomach. It is a double sheet: each sheet consists of two layers of peritoneum separated by a scant amount of connective tissue. The two sheets are folded back on themselves and are firmly adherent to each other. The anterior sheet descends from the greater curvature of the stomach and first part of the duodenum. The most anterior layer is continuous with the visceral peritoneum over the anterior surface of the stomach and duodenum and the posterior layer is continuous with the peritoneum over the posterior wall of the stomach and pylorus. The anterior sheet descends a variable distance into the peritoneal cavity and then turns sharply on itself to ascend as the posterior sheet. The posterior sheet passes anterior to the transverse colon and transverse mesocolon. It is attached to the posterior abdominal wall above the origin of the small intestinal mesentery and anterior to the head and body of the pancreas. The anterior layer of the posterior sheet is continuous with the peritoneum of the posterior wall of the lesser sac. The posterior layer is reflected sharply inferiorly and is continuous with the anterior layer of the transverse mesocolon. The posterior sheet is adherent to the transverse mesocolon at its root and is often known as the gastrocolic ligament, which is the
supracolic part of the greater omentum. In early fetal life the greater omentum and transverse mesocolon are separate structures, and this arrangement sometimes persists. During surgical mobilization of the transverse colon, the plane between the transverse mesocolon and greater omentum can be entered opposite the taenia omentalis, and the greater omentum can be separated entirely from the transverse colon and mesocolon if required. Access into the lesser sac can be obtained via this approach if the upper part of the posterior sheet of the greater omentum is then divided. This gives a relatively bloodless plane of entry for surgical access to the posterior wall of the stomach and to the anterior surface of the pancreas. The greater omentum is continuous with the gastrosplenic ligament on the left, and on the right it extends to the start of the duodenum. A fold of peritoneum, the hepatocolic ligament, may run from either the inferior surface of the right lobe of the liver or the first part of the duodenum to the right side of the greater omentum or hepatic flexure of the colon.

The right border of the greater omentum is occasionally adherent to the anterior surface of the ascending colon down as far as the caecum: its peritoneal layers are not continuous with the peritoneum over this part of the colon. A thin sheet of peritoneum referred to as Jackson's membrane may run from the front of the ascending colon and caecum to the posterolateral abdominal wall and may merge with the greater omentum. It often contains several small blood vessels. Occasionally, a band passes from the right side of the ascending colon to the lateral abdominal wall near the level of the iliac crest. It has been called the 'sustentaculum hepatis' but plays no role in the support of the liver. Other folds between the ascending colon and posterolateral abdominal wall may divide the right lateral paracolic gutter into several small recesses. Less commonly the greater omentum is adherent to the anterior surface of the left colon; very occasionally it extends to the level of the sigmoid colon.

When the undisturbed abdomen is opened, the greater omentum is frequently wrapped around the upper abdominal organs. Only rarely is it evenly dependent anterior to the coils of the small intestine, although this is the disposition which is frequently illustrated. It is usually thin and cribriform, but it always contains some adipose tissue and is a common site for storage of fat in obese individuals, particularly males.

Between the two layers of the anterior fold of the greater omentum, close to the greater curvature of the stomach, the right and left gastroepiploic vessels form a wide anastomotic arc. Numerous vessels are given off from the arc and extend the full length of the omentum. This supply appears to exceed the metabolic requirements of the omentum, and perhaps reflect the role the greater omentum may play in peritoneal disease processes. The greater omentum is highly mobile and frequently becomes adherent to inflamed viscera within the abdominal cavity. This action may help to limit the spread of infection and the omentum may provide a source of well-vascularized tissue to take part in the early reparative process. It contains numerous fixed macrophages, which are easily mobilized when activated and may accumulate into dense, oval or round visible 'milky-spots'.

The peritoneal connections of the spleen

The peritoneal connections of the spleen suspend the spleen in the left upper quadrant of the abdomen; they include the gastrosplenic, splenorenal and phrenicocolic ligaments. The gastrosplenic ligament runs between the greater
curvature of the stomach and the hilum of the spleen and is in continuity with the left side of the greater omentum. The layers of the gastroplenic ligament separate to enclose the spleen and then rejoin to form the splenorenal ligament and phrenicocolic ligaments. The splenorenal ligament extends from the spleen to the posterior abdominal wall and the phrenicocolic ligament extends to the anterolateral abdominal wall.

The splenorenal ligament is formed from two layers of peritoneum. The anterior layer is continuous medially with the peritoneum of the posterior wall of the lesser sac over the left kidney and runs up to the splenic hilum where it is continuous with the posterior layer of the gastroplenic ligament. The posterior layer of the splenorenal ligament is continuous laterally with the peritoneum over the inferior surface of the diaphragm and runs onto the splenic surface over the renal impression. The splenic vessels lie between the layers of the splenorenal ligament: the tail of the pancreas is usually present in its lower portion. The gastroplenic ligament also has two layers. The posterior layer is continuous with the peritoneum of the splenic hilum and the peritoneum over the posterior surface of the stomach. The anterior layer is formed from the peritoneum reflected off the gastric impression of the spleen and is continuous with the peritoneum over the anterior surface of the stomach. The short gastric and left gastroepiploic branches of the splenic artery, with their corresponding veins, pass between the layers of the gastroplenic ligament. The phrenicocolic ligament extends from the splenic flexure of the colon to the diaphragm at the level of the eleventh rib. It extends inferiorly and laterally and is continuous with the peritoneum of the lateral end of the transverse mesocolon at the lateral margin of the pancreatic tail, and the splenorenal ligament at the hilum of the spleen.

A fan-shaped presplenic fold frequently extends from the anterior aspect of the gastroplenic ligament near the greater curvature of the stomach below the inferolateral pole of the spleen and blends with the phrenicocolic ligament.

If the peritoneal attachments of the spleen are not recognized during surgery, the splenic capsule is at risk of injury and there may be subsequent serious bleeding. Downward traction on the phrenicocolic ligament during handling of the descending colon, especially during mobilization of the splenic flexure, may cause rupture of the splenic capsule. This is less likely if traction on the phrenicocolic ligament is made laterally or medially. The superior border and anterior diaphragmatic surface of the splenic capsule are often adherent to the peritoneum of the greater omentum. Medial traction on the omentum during surgery may cause splenic capsular injury: such injury is less likely, if any limited traction required is applied inferiorly.
PERITONEUM OF THE LOWER ABDOMEN

The posterior surface of the lower anterior abdominal wall is lined by parietal peritoneum, which extends from the linea alba centrally to the lateral border of quadratus lumborum. Here it is continuous with the peritoneum of the lateral paracolic gutter and is reflected over the sides and front of the ascending colon on the right and the descending colon on the left. Occasionally the ascending and descending colon are suspended by a short mesentery from the posterior abdominal wall. Between the ascending and descending colon, the peritoneum lines the posterior abdominal wall other than the oblique area, where it is reflected anteriorly to form the right and left layers of the small intestinal mesentery. Over the posterior abdominal wall it covers the left and right psoas major, inferior vena cava, duodenum, vertebral column and right and left ureters. At the upper extent of the posterior abdominal wall the peritoneum is reflected anteriorly and is continuous with the peritoneum of the posterior layer of the transverse mesocolon.

**Transverse mesocolon**

The mesentery of the transverse colon is a broad fold of visceral peritoneum reflected anteriorly from the posterior abdominal wall and suspends the transverse colon in the peritoneal cavity. The root of the transverse mesocolon lies along an oblique line passing from the anterior aspect of the second part of the duodenum, over the head and neck of the pancreas, above the duodenojejunal junction and over the upper pole of the left kidney to the splenic flexure (Fig. 64.1). It varies considerably in length but is shortest at either end. It contains the middle colic vessels and their branches together with branches of the superior mesenteric plexus, lymphatics and regional lymph nodes. Its two layers pass to the posterior surface of the transverse colon, where they separate to cover the colon. The upper layer of peritoneum is reflected from the posterior abdominal wall immediately anteriorly and inferiorly and becomes continuous with the posterior layer of the greater omentum to which it is adherent. The lower layer of peritoneum of the transverse mesocolon is continuous with the peritoneum of the posterior abdominal wall. Lateral extensions of the transverse mesocolon produce two shelf-like folds on the right and left sides of the abdominal cavity. On the right the duodenocecolic ligament extends from the transverse mesocolon at the hepatic flexure to the second part of the duodenum. On the left the phrenicocolic ligament extends from the transverse mesocolon at the splenic flexure to the diaphragm at the level of the eleventh rib. The root of the transverse mesocolon is closely related to the upper limit of the root of the mesentery of the small intestine near the uncinate process of the pancreas.

**Mesentery of the small intestine**
The mesentery of the small intestine is arranged as a complex fan formed from two layers of peritoneum (anterosuperior and posteroinferior) separated by connective tissue and vessels. The root of the mesentery lies along a line running diagonally from the duodenojejunal flexure on the left side of the second lumbar vertebral body to the right sacroiliac joint (Fig. 64.1). The root crosses over the third part of the duodenum, aorta, inferior vena cava, right ureter and right psoas major. The average length of the root of the mesentery is 15 cm in adults; while along its intestinal attachment is the same length as the small intestine (approximately 5 m), and consequently the mesentery is usually thrown into multiple folds along its intestinal border. The average depth of the mesentery from the root to the intestinal border is 20 cm, but this varies along the length of the small intestine: it is shortest at the jejunum and terminal ileum and longest in the region of the mid ileum. Its two peritoneal layers contain the jejunum, ileum, jejunal and ileal branches of the superior mesenteric vessels, branches of the superior mesenteric plexus, lacteals and regional lymph nodes. Because of the length and mobility of the mesentery, identification of the proximal and distal ends of a loop of small intestine may be difficult through small surgical incisions. Tracing the continuity of the right peritoneal layer of the mesentery onto the posterior abdominal wall above the root towards the ascending colon, and the continuity of the left layer towards the descending and sigmoid colon, may be useful in helping to orientate an individual loop of ileum. The mesentery of the small intestine is sometimes joined to the transverse mesocolon at the duodenojejunal junction by a peritoneal band. Occasionally the fourth part of the duodenum possesses a very short mesentery which is continuous with the upper end of the root of the small bowel mesentery. Pronounced bands of peritoneum may extend to the posterior abdominal wall at the terminal ileum. The root of the mesentery of the small intestine is continuous with the peritoneum surrounding the appendix and caecum in the right iliac fossa.

**Mesoappendix**

The mesentery of the appendix is a triangular fold of peritoneum around the vermiform appendix, attached to the posterior surface of the lower end of the mesentery of the small intestine close to the ileocaecal junction. It usually reaches the tip of the appendix but sometimes fails to reach the distal third, in which case a vestigial low peritoneal ridge containing fat is present over the distal third. It encloses the blood vessels, nerves and lymph vessels of the vermiform appendix, and usually contains a lymph node.

**Sigmoid mesocolon**

The sigmoid mesocolon shows individual variation in length and depth. The root of the sigmoid colon forms a shallow inverted V with an apex near the division of the left common iliac artery but may vary from a very short straight line at the pelvic brim to a long curved attachment. The upper, left end of the
attachment runs medially over the left psoas major. The lower, right end passes into the pelvis towards the midline at the level of the third sacral vertebra. The root extends for a variable distance over the brim of the pelvis and the lower posterior abdominal wall. The anteromedial peritoneal layer of the mesentery of the sigmoid colon is continuous with the peritoneum of the lower left posterior abdominal wall and its posterolateral layer is continuous with the peritoneum of the pelvis and lateral abdominal wall. The proximal and distal ends of the sigmoid colon are occasionally joined together by a fibrous band which is usually associated with a narrow based sigmoid mesentery and may predispose the sigmoid colon to volvulus. Pronounced bands of peritoneum may also be found running from the proximal sigmoid colon to the posterior abdominal wall. The sigmoid and superior rectal vessels run between its layers and the left ureter descends into the pelvis behind its apex.
PERITONEUM OF THE LOWER ANTERIOR ABDOMINAL WALL

The peritoneum of the lower anterior abdominal wall is raised into five ridges which diverge as they descend from the umbilicus. These are the median and right and left lateral and medial umbilical folds (Fig. 64.6). The median umbilical fold extends from the umbilicus to the apex of the bladder and contains the urachus or its remnant (Ch. 78). The obliterated umbilical artery lies under the medial umbilical fold which ascends from the pelvis to the umbilicus. The supravesical fossa lies between the medial and median umbilical folds on either side of the midline. The lateral umbilical fold covers the inferior epigastric artery and vein below their entry into the rectus sheath, and is separated from the medial umbilical fold by the medial inguinal fossa. The lateral inguinal fossa lies lateral to the lateral umbilical fold, and covers the deep inguinal ring. The femoral fossa lies inferomedial to the lateral inguinal fossa, from which it is separated by the medial end of the inguinal ligament. It overlies the femoral ring (see Ch. 61).
**Fig. 64.6** The infra-umbilical part of the anterior abdominal wall of a male subject: posterior surface, with the peritoneum *in situ*. Note the pelvic bones flanking the wide greater pelvis (middle) and narrower lesser pelvis (below) containing the bladder.
PERITONEUM OF THE PELVIS

The parietal peritoneum of the posterior surface of the anterior abdominal wall and that lining the posterior abdominal wall continue into the pelvis as the pelvic peritoneum. The pelvic peritoneum then follows the surfaces of the true pelvic viscera and pelvic side walls although there are important differences between the sexes.

Peritoneum of the male pelvis

In males, the peritoneum of the left lower abdominal wall is reflected from the junction of the sigmoid colon and anterolateral surface of the rectum to line the brim and upper inner surface of the true pelvis (Fig. 64.7). The peritoneum passes down into the true pelvis, lying over the anterior surface of the rectum, which then becomes an extraperitoneal organ. Laterally, the peritoneum is reflected to the pelvic side walls to form the right and left pararectal fossae: these vary in size according to the degree of distension of the rectum. The peritoneum is reflected anteriorly from the anterior surface of the rectum over the upper poles of the seminal vesicles and onto the posterior surface of the bladder, producing the rectovesical pouch. Anteriorly the rectovesical pouch is limited laterally by peritoneal folds, the sacrogenital folds, which extend from the sides of the bladder posteriorly to the anterior aspect of the sacrum. The peritoneum covers the superior surface of the bladder, and forms a paravesical fossa on each side limited laterally by a ridge of peritoneum which contains the ductus deferens. The size of the paravesical fossae depends on the volume of urine in the bladder. When the bladder is empty, a variable transverse vesical fold divides each fossa into two. The anterior ends of the sacrogenital folds may sometimes be joined by a ridge separating a middle fossa from the main rectovesical pouch. Between the paravesical and pararectal fossae the ureters and internal iliac vessels may cause slight elevations in the peritoneum. From the apex of the bladder the peritoneum extends superiority along the posterior surface of the lower anterior abdominal wall to the umbilicus. When the bladder distends, the peritoneum is lifted from the lower anterior abdominal wall so that part of the anterior surface of the bladder is in direct contact with the posterior surface of the lower median area of the anterior abdominal wall. This relationship means that a well-distended bladder can be entered by direct puncture through the lower anterior abdominal wall without entering the peritoneal cavity (suprapubic puncture).
In females the peritoneum covers the upper rectum as it does in the male, but it descends further over the anterior surface of the rectum. The lateral limit of the pararectal and paravesical fossae is the peritoneum covering the round ligament of the uterus. The rectovesical pouch is occupied by the uterus and vagina. The peritoneum from the rectum is thus reflected anteriorly onto the posterior surface of the posterior fornix of the vagina and the uterus, producing the recto-uterine pouch (of Douglas). The peritoneum covers the fundus of the uterus to its anterior (vesical) surface as far as the junction of the body and cervix, from which it is reflected forwards to the upper surface of the bladder, forming a shallow vesico-uterine pouch. Peritoneum is reflected from the bladder to the posterior surface of the anterior abdominal wall as it is in males. Marginal recto-uterine folds correspond to the sacrogenital folds in males and pass back to the sacrum from the sides of the cervix, lateral to the rectum. Peritoneum is reflected from the anterior and posterior uterine surfaces to the lateral pelvic walls as the broad ligament of the uterus (see Fig. 77.18). This consists of anteroinferior and posterosuperior layers which are continuous at the upper border of the ligament. The broad ligament extends from the sides of the uterus to the lateral pelvic walls, and contains the uterine tubes in its free superior margins and the ovaries attached to its posterior layer. Below, it is continuous with the lateral pelvic parietal peritoneum. Between the ridges formed by the obliterated umbilical arteries and the ureter, the peritoneum forms a shallow depression on the lateral pelvic wall, the ovarian fossa, which lies behind the lateral attachment of the broad ligament. The ovary usually rests in the fossa in nulliparous females.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Parietal and visceral peritoneum develop from the somatopleural and splanchnopleural layers respectively of lateral plate mesoderm (see Ch. 73). Parietal peritoneum is therefore supplied by somatic blood vessels of the abdominal and pelvic walls and its lymphatics join those in the body wall and drain to parietal lymph nodes. Visceral peritoneum is best considered as an integral part of the viscera which it overlies; it derives its blood supply from the viscera, and its lymphatics join the visceral vessels to drain to the regional lymph nodes.
INNERVATION

The parietal peritoneum is innervated by branches from somatic efferent and afferent nerves that also supply the muscles and skin respectively of the overlying body wall. The visceral peritoneum is innervated by branches of visceral afferent nerves which travel with the autonomic supply to the underlying viscera. The different sensations arising from pathologies which affect either the parietal or visceral peritoneum reflect these differences in patterns of innervation. Well-localized pain is elicited by mechanical, thermal or chemical stimulation of the nociceptors of the parietal peritoneum. The sensation is usually confined to one or two dermatomes for each area of peritoneum stimulated and is both lateralized and well localized. Somatic nerves that innervate the parietal peritoneum also supply the corresponding segmental areas of skin and muscles; when the parietal peritoneum is irritated, muscles tend to contract reflexly, causing localized hypercontractility (guarding) or even rigidity of the abdominal wall. The parietal diaphragmatic peritoneum is supplied with afferent fibres from the phrenic nerves (centrally) and by the lower six intercostal nerves and subcostal nerves (peripherally): peripheral irritation of the diaphragm may therefore result in pain, tenderness and muscular rigidity in the distribution of the lower thoracic spinal nerves, while central irritation may result in pain in the cutaneous distribution of the third to fifth cervical spinal nerves, i.e. the shoulder region.

The visceral peritoneum and viscera are not affected by these stimuli because the visceral afferent innervation provides a much more limited sensation of discomfort. When stimulated, the sensation of pain is of a less severe nature and is referred to the area of abdominal wall according to the region of the intestinal tract affected. Discomfort from structures derived from the foregut is felt in the region of the epigastrium, from midgut structures in the region of the umbilicus, and from hindgut structures in the suprapubic region: none of these sensations shows significant lateralization. However, stretch of the visceral peritoneum is a potent cause of certain sensations and responses. Various neural elements in the visceral walls, mesenteries and overlying peritoneum mediate poorly localized sensations of discomfort when stimulated by stretch, and may also elicit profound reflex autonomic reactions involving vasomotor and cardiac changes. This is of considerable clinical relevance. The effects of division of the parietal peritoneum may be rendered painless by local or regional local anaesthesia. In marked contrast, the direct central connections of the visceral afferents, particularly via the vagus, mean that stretching the visceral peritoneum may have profound effects, and may produce acute haemodynamic instability despite high spinal anaesthesia. Ischaemia of the underlying viscera causes poorly localized abdominal pain, probably due to the spasms of visceral smooth muscle.
GENERAL ARRANGEMENT OF THE PERITONEAL CAVITY

The peritoneal cavity is a single continuous space between the parietal peritoneum lining the abdominal wall and the visceral peritoneum enveloping the abdominal organs. It consists of a main region, termed the greater sac, which is equivalent to the main abdominal cavity surrounding the majority of the abdominal and pelvic viscera. The lesser sac, or omental bursa, is a small diverticulum lined with peritoneum, which is situated behind the stomach and lesser omentum and in front of the pancreas and retroperitoneum. These two areas communicate via the epiploic foramen.

For clinical purposes the peritoneal cavity can be divided into several spaces because pathological processes are often contained within these spaces and their anatomy may influence diagnosis and treatment. It is useful to divide the peritoneal cavity into two main compartments, supramesocolic and inframesocolic, which are partially separated by the transverse colon and its mesentery (the latter connects the transverse colon to the posterior abdominal wall). The pelvic peritoneal spaces are described above.

SUPRAMESOCOLIC COMPARTMENT

The supramesocolic space lies above the transverse mesocolon between the diaphragm and the transverse colon. It can be arbitrarily divided into right and left supramesocolic spaces. These regions can be further subdivided into a number of subspaces, which are normally in communication, but are frequently subdivided by inflammatory adhesions in disease. The right supramesocolic space can be divided into three subspaces; the right subphrenic space, the right subhepatic space, and the lesser sac. The left supramesocolic space can be divided into two subspaces; the left subphrenic space and the left perihepatic space.

Right subphrenic space

The right subphrenic space lies between the diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver. It is bounded on the left side by the falciform ligament and behind by the upper layer of the coronary ligament. It is a relatively common site for collections of fluid after right sided abdominal inflammation.

Right subhepatic space (hepatorenal recess)

The right subhepatic space lies between the right lobe of the liver and the right kidney. It is bounded superiorly by the inferior layer of the coronary ligament, laterally by the right lateral abdominal wall, posteriorly by the anterior surface of the upper pole of the right kidney and medially by the second part of the duodenum, hepatic flexure, transverse mesocolon and
part of the head of the pancreas. In the supine position the posterior right subhepatic space is more dependent than the right paracolic gutter: postoperative infected fluid collections are common in this location.

**Lesser sac (omental bursa)**

The lesser sac is a cavity lined with peritoneum and connected to the larger general peritoneal cavity (greater sac) by the epiploic foramen. It is considered part of the right supramesocolic space because embryologically the liver grows into the right peritoneal space and stretches the dorsal mesentery to form the lesser sac behind the stomach. The sac varies in size according to the size of the viscera making up its walls. It has posterior and anterior walls as well as superior, inferior, right and left borders.

The anterior wall is made up of the posterior peritoneal layer of the lesser omentum, the peritoneum over the posterior wall of the stomach and first part of the duodenum, and the uppermost part of the anterior layer of the greater omentum. At its right border, the anterior wall is mostly formed by the lesser omentum but moving towards the left, the lesser omentum becomes progressively shorter and more of the anterior wall is formed by the posterior aspect of the stomach and greater omentum.

The posterior wall is formed mainly by the peritoneum covering the posterior abdominal wall in this area. In the lower part, the posterior wall is made up of the anterior layer of the posterior sheet of the greater omentum as it lies on the transverse mesocolon. The posterior wall covers, from below upwards, a small part of the head and the whole neck and body of the pancreas, the medial part of the anterior aspect of the left kidney, most of the left suprarenal gland, the commencement of the abdominal aorta and coeliac artery and part of the diaphragm. The inferior phrenic, splenic, left gastric and hepatic arteries lie partly behind the bursa. Many of these structures form the ‘bed’ of the stomach and are separated from it only by the linings of the lesser sac.

The superior border of the lesser sac is narrow and lies between the right side of the oesophagus and the upper end of the fissure for the ligamentum venosum. Here peritoneum of the posterior wall of the lesser sac is reflected anteriorly from the diaphragm to join the posterior layer of the lesser omentum.

The inferior border of the lesser sac runs along the line of the fusion of the layers of the greater omentum. This runs from the gastroepiploic ligament to the peritoneal fold behind the first part of the duodenum. In cases where the layers are not completely adherent to each other, the lesser sac may extend as far as the bottom of the two sheets of the greater omentum. In adults, even in these circumstances of separation of the layers, the lowest extent of
the inferior border is rarely below the level of the transverse colon.

The right border of the lesser sac is formed by the reflection of the peritoneum from the pancreatic neck and head onto the inferior aspect of the first part of the duodenum. The line of this reflection ascends to the left, along the medial side of the gastroduodenal artery. Near the upper duodenal margin the right border joins the floor of the epiploic foramen round the hepatic artery proper. The epiploic foramen thus forms a break in the right border. Above the epiploic foramen the right border is formed by the reflection of peritoneum from the diaphragm to the right margin of the caudate lobe of the liver and along the left side of the inferior vena cava, enclosing the hepatic recess.

The left border of the lesser sac runs from the left end of the root of the transverse mesocolon and is mostly formed by the inner layer of peritoneum of the splenorenal and gastrosplenic ligaments. The part of the lesser sac lying between the splenorenal and gastrosplenic ligaments is referred to as the splenic recess. Above the level of the spleen, the two ligaments are merged as the short gastrophrenic ligament, which passes forwards from the diaphragm to the posterior aspect of the fundus of the stomach and forms part of the upper left border of the lesser sac. The two layers of the gastrophrenic ligament diverge near the abdominal oesophagus, leaving part of the posterior gastric surface devoid of peritoneum. The left gastric artery runs forwards here into the lesser omentum.

The lesser sac is narrowed by two crescentic peritoneal folds produced by the hepatic and left gastric arteries. The left gastropancreatic fold overlies the left gastric artery as it runs from the posterior abdominal wall to the lesser curvature of the stomach. The right gastropancreatic fold overlies the hepatic artery as it runs from the posterior abdominal wall to the lesser omentum. The folds vary in size. When prominent, they divide the lesser sac into a smaller superior and a larger inferior recess. The superior recess lies posterior to the lesser omentum and liver, and encloses the caudate lobe of the liver, which is covered by peritoneum on both its anterior and posterior surfaces. It extends superiorly into the fissure for the ligamentum venosum and lies adjacent to the right crus of the diaphragm posteriorly. The inferior recess of the lesser sac lies between the stomach and pancreas and is contained in the double sheet of the greater omentum.

*Epiploic foramen (of Winslow)*

The epiploic foramen (foramen of Winslow, aditus to the lesser sac), is a short, vertical slit, usually 3 cm in height in adults, in the upper part of the right border of the lesser sac. It leads into the greater sac. The hepatoduodenal ligament, which is formed by the thickened right edge of the lesser omentum extending from the flexure between the first and second
parts of the duodenum, forms the anterior margin of the foramen. The anterior border contains the common bile duct (on the right), portal vein (posteriorly) and hepatic artery (on the left) between its two layers. Superiorly the peritoneum of the posterior layer of the hepatoduodenal ligament runs over the caudate lobe of the liver which forms the roof of the epiploic foramen. This layer of peritoneum is then reflected onto the inferior vena cava which forms the posterior margin of the epiploic foramen. At the upper border of the first part of the duodenum the peritoneum runs forwards from the inferior vena cava, above the head of the pancreas, and is continuous with the posterior layer of the lesser omentum, forming the floor of the epiploic foramen. A narrow passage, the vestibule of the lesser sac, may be found to the left of the foramen between the caudate process and the first part of the duodenum. To the right, the rim of the foramen is continuous with the peritoneum of the greater sac. The roof is continuous with the peritoneum on the inferior surface of the right hepatic lobe. The anterior and posterior walls of the foramen are normally apposed.

Left subphrenic space

The left subphrenic space lies between the diaphragm, the anterior and superior surfaces of the left lobe of the liver, the anterosuperior surface of the stomach and the diaphragmatic surface of the spleen. It is bounded to the right by the falciform ligament and behind by the anterior layer of the left triangular ligament. It is much enlarged in the absence of the spleen and is a common site for fluid collection particularly after splenectomy. The left subphrenic space is substantially larger than the right and is sometimes described as being divided into anterior and posterior parts, although no obvious demarcation exists in the absence of disease. The left posterior subphrenic space is small and lies between the fundus of the stomach and the diaphragm above the origin of the splenorenal ligament. The left anterior subphrenic space is large and lies between the superior and anterolateral surfaces of the spleen and the left dome of the diaphragm. Inferiorly and medially, this space is bounded by the splenorenal, gastroplenic, and phrenicocolic ligaments which produces a partial barrier to the left paracolic gutter. This may explain why left subphrenic collections are less frequent than right subphrenic collections following lower abdominal and pelvic surgery, but the left subphrenic space is the commonest site of fluid collection after upper abdominal, particularly splenic, surgery.

Left perihepatic space

The left perihepatic space is sometimes subdivided into anterior and posterior spaces. The posterior perihepatic space is also known as the left subhepatic space or gastrohepatic recess. The left anterior perihepatic space lies between the anterosuperior surface of the left lobe of the liver and diaphragm. The left posterior perihepatic space lies inferior to the left lobe of
the liver, and extends into the fissure for the ligamentum venosum on the right, anterior to the main portal vein. Posteriorly, the lesser omentum separates this space from the superior recess of the lesser sac. On the left, the space is bounded by the lesser curvature of the stomach.
INFRAMESOCOLIC COMPARTMENT

The inframesocolic compartment lies below the transverse mesocolon and transverse colon are far as the true pelvis. It is divided in two unequal spaces by the root of the mesentery of the small intestine. It contains the right and left paracolic gutters lateral to the ascending and descending colon. As a consequence of the mobility of the transverse mesocolon and mesentery of the small intestine, disease processes are rarely well contained within these spaces, and fluid within the infracolic space tends to descend into the pelvis or the paracolic gutters.

Right infracolic space

The right infracolic space is a triangular space. It is smaller than its counterpart on the left, and lies posterior and inferior to the transverse colon and mesocolon and to the right of the small intestinal mesentery. The space is narrowest inferiorly because the attachment of the root of the mesentery of the small intestine lies well to the right of the midline. The vermiform appendix often lies in the lower part of the right infracolic space.

Left infracolic space

The left infracolic space is larger than its counterpart on the right and is in free communication with the pelvis to the right of the midline. It lies posterior and inferior to the transverse colon and mesocolon and to the left of the mesentery of the small intestine. The sigmoid colon and its mesentery may partially restrict the flow of fluid or blood into the pelvis to the left of the midline.

Paracolic gutters

The right and left paracolic gutters are peritoneal recesses on the posterior abdominal wall lying alongside the ascending and descending colon. The main paracolic gutter lies lateral to the colon on each side. A less obvious medial paracolic gutter may be formed, especially on the right side, if the colon possesses a short mesentery for part of its length. The right (lateral) paracolic gutter runs from the superolateral aspect of the hepatic flexure of the colon, down the lateral aspect of the ascending colon, and around the caecum. It is continuous with the peritoneum as it descends into the pelvis over the pelvic brim. Superiorly, it is continuous with the peritoneum which lines the hepatorenal pouch and, through the epiploic foramen, the lesser sac. Bile, pus or blood released from viscera anywhere along its length may run along the gutter and collect in sites quite remote from the organ of origin. In supine patients, infected fluid from the right iliac fossa may ascend in the gutter to enter the lesser sac. In patients nursed in a sitting position, fluid from the stomach, duodenum or gallbladder may run down the gutter to
collect in the right iliac fossa or pelvis and may mimic acute appendicitis or form a pelvic abscess. The right paracolic gutter is larger than the left, which together with the partial barrier provided by the phrenicocolic ligament, may explain why right subphrenic collections are more common than left subphrenic collections.

**Extraperitoneal subphrenic spaces**

There are two potential ‘spaces’ which actually lie outside the peritoneal coverings of the abdomen, but are of clinical relevance because of the possibility that fluid collections will accumulate in them. The right extraperitoneal space is bounded by the two layers of the coronary ligament, the bare area of the liver and the inferior surface of the right dome of the diaphragm. The left extraperitoneal space lies anterior to the left suprarenal gland and upper pole of the left kidney. It contains extraperitoneal connective tissue.
RECESSES OF THE PERITONEAL CAVITY

Peritoneal folds may create fossae or recesses within the peritoneal cavity. These are of clinical interest because a length of intestine may enter one and be constricted by the fold at the entrance to the recess; it may subsequently become a site of internal herniation. The contents of the peritoneal fold may be important if surgical incision is required to reduce such a hernia. Although internal herniation may occur into the lesser sac via the epiploic foramen, the sac is not usually considered to be a peritoneal recess.

Duodenal recesses

Several folds of peritoneum may exist around the fourth part of the duodenum and the duodenojejunal junction forming a number of named recesses (Fig. 64.8).

Fig. 64.8  The superior and inferior duodenal recesses. The transverse colon and jejunum have been displaced.

Superior duodenal recess

The superior duodenal recess is occasionally present, usually in association with an inferior duodenal recess. It lies to the left of the end of the fourth part of the duodenum, opposite the second lumbar vertebra, and behind a crescentic superior duodenal fold (duodenojejunal fold). The fold has a semilunar free lower edge which merges to the left with the peritoneum anterior to the left kidney. The inferior mesenteric vein is directly behind the junction of the left (lateral) end of this fold and the posterior parietal peritoneum. The recess varies in size but is commonly 2 cm deep, admitting a fingertip. It opens downwards, its orifice being in the angle formed
by the left renal vein as it passes across the abdominal aorta.

**Inferior duodenal recess**

The inferior duodenal recess is usually present often associated with a superior recess with which it may share an orifice. It lies to the left of the fourth part of the duodenum, opposite the third lumbar vertebra. It sits behind a non-vascular, triangular inferior duodenal fold (duodenomesocolic fold), which has a sharp upper edge. It is usually 3 cm deep, admits one or two fingers and opens upwards towards the superior duodenal recess. It sometimes extends behind the fourth part of the duodenum and to the left, in front of the ascending branch of the left colic artery and the inferior mesenteric vein.

**Paraduodenal recess**

The paraduodenal recess may occur in conjunction with superior and inferior duodenal recesses. It is rare in adults but is more commonly seen in newborn children. It lies a little to the left and slightly behind of the fourth part of the duodenum, behind a falciform paraduodenal fold. The free right edge of the fold contains the inferior mesenteric vein and ascending branch of the left colic artery, and represents part of the upper left colic mesentery. Its free edge lies in front of the wide orifice of the recess, which faces right.

**Retroduodenal recess**

The retroduodenal recess is the largest of the duodenal recesses, but is rarely present. It lies behind the third and fourth parts of the duodenum in front of the abdominal aorta. It ascends nearly to the duodenojejunal junction, is 8–10 cm deep, and bounded on both sides by duodenoparietal folds. It has a wide orifice which faces down and to the left.

**Duodenojejunal recess**

The duodenojejunal or mesocolic recess typically occurs in 20% of adults. When present, it is almost never associated with any other duodenal recesses. It is approximately 3 cm deep and lies to the left of the abdominal aorta, between the duodenojejunal junction and the root of the transverse mesocolon. It is bounded above by the pancreas, on the left by the kidney, and below by the left renal vein. It has a circular opening between two peritoneal folds, and faces down and to the right.

**Mesentericoparietal recess**

The mesentericoparietal recess is only rarely present. It lies just below the third part of the duodenum and invaginates into the upper part of the mesentery towards the right. Its orifice is large and faces left behind a fold of mesentery raised by the superior mesenteric artery.

**Caecal recesses**

Several folds of peritoneum may exist around the caecum and form recesses (Fig. 64.9). Paracaecal recesses are common sites for abscess formation following acute appendicitis.
Superior ileocaecal recess

The superior ileocaecal recess is usually present and best developed in children. It is often reduced and absent in the aged, especially the obese. It is formed by the vascular fold of the caecum, which arches over the anterior caecal artery, supplying the anterior part of the ileocaecal junction, and its accompanying vein. It is a narrow slit bounded in front by the vascular fold, behind by the ileal mesentery, below by the terminal ileum and on the right by the ileocaecal junction. Its orifice opens downwards to the left.

Inferior ileocaecal recess

The inferior ileocaecal recess is well marked in youth but frequently obliterated by fat in adults. It is formed by the ileocaecal fold, which extends from the anteroinferior aspect of the terminal ileum to the front of the mesoappendix (or to the appendix or caecum). It is also known as the ‘bloodless fold of Treves’, although it sometimes contains blood vessels and will often bleed if divided during surgery. If inflamed, especially when the appendix and its mesentery are retrocaecal, it may be mistaken
for the mesoappendix. The recess is bounded in front by the ileocaecal fold, above by
the posterior ileal surface and its mesentery, to the right by the caecum, and behind
by the upper mesoappendix. Its orifice opens downwards to the left.

**Retrocaecal recess**

The retrocaecal recess lies behind the caecum. It varies in size and extent and
ascends behind the ascending colon, often being large enough to admit an entire
finger. It is bounded in front by the caecum (and sometimes the lower ascending
colon), behind by the parietal peritoneum and on each side by caecal folds
(parietocolic folds) passing from the caecum to the posterior abdominal wall. The
vermiform appendix frequently occupies this recess when in the retrocaecal position.

**Intersigmoid recess**

The intersigmoid recess is constant in fetal life and infancy, but may disappear during
later development. It lies behind the apex of the V-shaped parietal attachment of the
sigmoid mesocolon and is funnel shaped. It is directed upwards and opens
downwards. It varies in size from a slight depression to a shallow fossa. Its posterior
wall is formed by the parietal peritoneum of the posterior abdominal wall which covers
the left ureter as it crosses the bifurcation of the left common iliac artery. Occasionally
the recess is within the layers of the sigmoid mesocolon, and is nearer the bowel wall
than the mesenteric root. It is probably produced by an imperfect blending of the
mesocolon with the posterior parietal peritoneum.
CLINICAL MANAGEMENT OF FLUID COLLECTIONS IN THE PERITONEAL CAVITY

Fluid collections frequently occur within the peritoneal cavity as a result of a wide range of pathological processes. In the absence of any inflammation, peritoneal adhesions or previous surgery, serous fluid is almost always distributed freely between the peritoneal spaces and is not confined to any particular area. Simple ascites, for example, can therefore be drained freely from any convenient dependent part of the peritoneal cavity. This is most commonly performed by blind or ultrasound guided insertion of a catheter into the lower left or right paracolic gutters, which usually readily fill with fluid. The colon and some loops of small bowel may be present, but their relatively mobility ensures that they are very unlikely to be injured during this procedure.

Fluid collections caused by inflammatory processes are often much more viscid because they contain pus, fibrin or blood and are usually associated with peritoneal inflammation which results in, at least transient, peritoneal adhesions. These factors mean that collections may become localized if the flow of fluid is restricted by the partial compartmentalization of the peritoneum. Once collected in a particular 'space', this fluid often becomes further confined by ongoing inflammation and may even form a truly walled-off cavity over time. Any of the spaces of the peritoneum may develop a collection, but the subphrenic, subhepatic and pelvic spaces are the commonest since they are most well defined by the fixed peritoneal folds and organs forming their boundaries. These spaces are also the most dependent spaces within the peritoneum in the supine position and consequently any initially free fluid tends to gravitate to them.

Surgical access to the peritoneal spaces is rarely necessary today because of the great advances which have been made in radiologically guided drainage. When necessary, lateral subcostal or intercostal incisions may give adequate access to the subphrenic spaces and the anterior wall of the rectum is also a useful route to access the rectouterine or rectovesical space. Computerized tomography or ultrasound guided drainage offers a much more reliable and versatile method of accessing even difficult spaces such as subhepatic, perihepatic, paracolic or even intermesenteric collections. Posterolateral translumbar or trans-sciatic approaches can be used to access these more difficult areas.

Peritoneal dialysis

The mesothelium resembles vascular endothelium in being a dialysing membrane which fluids and small molecules may traverse. Numerous endocytic vesicles occur near the cell surfaces, and the remaining cytoplasm is poor in organelles, indicating low metabolic activity. Normally the volumes
of fluid transmitted by peritoneal surfaces are small, but large volumes may be administered via the intraperitoneal route. Conversely, substances such as urea can be dialysed from blood into fluid circulated through the peritoneal cavity.

**Ventriculoperitoneal shunts**

The absorptive capabilities of the peritoneum can be used to absorb excess transitional fluids from several sites in the body. The commonest of these is the absorption of cerebrospinal fluid drained from the intracerebral ventricles or the intrathecal space via a fine calibre catheter. The catheter can be placed within the peritoneum with a one way valve preventing reflux of peritoneal fluid into the cerebrospinal fluid. The fluid is then continuously absorbed, maintaining a low pressure within the intrathecal or intraventricular space.

The abdominal oesophagus is 1–2.5 cm in length, and is slightly broader at the cardiac orifice than the diaphragmatic aperture. It lies to the left of the midline and enters the abdomen through the oesophageal aperture (formed by the two diaphragmatic crura) opposite the level of the tenth thoracic vertebra. It runs obliquely to the left and slightly posteriorly, and ends at the gastro-oesophageal junction/cardiac orifice of the stomach. The abdominal oesophagus lies posterior to the left lobe of the liver, which it grooves slightly, anterior to the left crus, the left inferior phrenic vessels and the left greater splanchnic nerve; its surface is covered in a thin layer of connective tissue and visceral peritoneum which contains the anterior and posterior vagi as well as the oesophageal branches of the left gastric vessels. The anterior vagus may be single or composed of multiple trunks, and is closely related to the outer fibres of the longitudinal muscle coat of the oesophagus. The posterior vagus is usually a single trunk and is less closely applied to the oesophageal muscle within the loose connective tissue, which makes its identification during surgery somewhat easier.

The abdominal oesophagus is effectively tethered to the diaphragm by connective tissue (Fig. 65.1); the phreno-oesophageal ligament. This is formed of two thickened bands of elastin-rich connective tissue; the inferior phreno-oesophageal ligament is effectively an extension of the transversalis fascia extending beneath the parietal peritoneum as it is reflected from the diaphragm onto the abdominal oesophagus. The fibres are only loosely attached to the adventitial tissues and a variable amount of fat often lies beneath it, between the oesophageal wall and the crural sling. This oesophageal fat pad tends to act to tether the oesophagus to the fibres of the crura but tends to regress with age. On the thoracic side of the diaphragm the superior phreno-oesophageal ligament is similarly formed from an extension of the subpleural endothoracic fascia. It is denser than its inferior counterpart with more elastin present and is tethered much more firmly through the muscle fibres of the oesophageal wall into the submucosal tissues. It may well act to restore lower oesophageal position after the movement engendered by the peristalsis of swallowing (Kwok et al 1999). Anteriorly, the subperitoneal connective tissue is particularly dense and blends with both the outer layer of the oesophageal wall and the apex of the crural fibres of the diaphragm. On the posterior aspect the peritoneal reflection is extremely short since the crura lie steeply angled, and the posterior oesophageal wall has a much shorter ‘effective length’ than the anterior. This short reflection of peritoneum is sometimes referred to as the gastrophrenic ligament and, via the peritoneum over the oesophagus continues directly onto the posterior surface of the stomach. It covers the oesophageal branches of the left gastric vessels and the coeliac branches of the posterior vagus and can thus be said to form an extremely short, wide mesentery to the abdominal oesophagus. In all but the thinnest individuals a pad of adipose tissue is found beneath the peritoneum covering the anterior surface of the lower abdominal oesophagus and the adjacent gastric wall. It is a useful surgical marker for the external location of the gastro-oesophageal junction.
**VASCULAR SUPPLY AND LYMPHATIC DRAINAGE**

**Arteries**

The abdominal oesophagus is supplied by oesophageal branches of the left gastric artery. These ascend as an anterior and posterior branch beneath the visceral peritoneum to supply perforating branches to the intramural and submucosal plexuses. The posterior surface usually receives an additional supply
via branches of the upper short gastric arteries, the terminal branches of the oesophageal branches of the thoracic aorta and occasionally an ascending branch of the posterior gastric artery.

**Veins**

Veins drain via plexuses to the left gastric and upper short gastric veins (see Stomach veins below).

**Lymphatic drainage**

Lymphatic drainage occurs to the left gastric and left and right paracardial nodes and from the posterior surface directly to the uppermost para-aortic nodes (see Fig. 65.13).
**Fig. 65.13** Main lymph node stations of the stomach and upper abdominal viscera. The sagittal relationships of the node groups around the neck of the pancreas are shown bottom right. The para-aortic nodes are among the highest nodes for these viscera but have been removed for clarity (see Ch. 66).
INNERVATION

The abdominal oesophagus is innervated by sympathetic and parasympathetic fibres. The parasympathetic fibres are derived directly from the peri-oesophageal thoracic plexus and to a lesser extent from the anterior and posterior vagi. They are motor to the distal oesophagus and both stimulatory and inhibitory to the functional lower oesophageal sphincter (LOS), maintaining both background tone and co-ordinating distal oesophageal peristalsis with relaxation of the LOS during swallowing. The sympathetic supply originates from the fifth to 12th thoracic spinal segments and is mainly distributed via the greater and lesser splanchnic nerves and the coeliac plexus.
STOMACH

The stomach is the widest part of the alimentary tract and lies between the oesophagus and the duodenum. It is situated in the upper abdomen, extending from the left upper quadrant downwards, forwards and to the right, lying in the left hypochondriac, epigastric and umbilical areas. It occupies a recess beneath the diaphragm and anterior abdominal wall that is bounded by the upper abdominal viscera on either side. The mean capacity of the stomach increases from approximately 30 ml at birth, to 1000 ml at puberty, and approximately 1500 ml in adults. The peritoneal surface of the stomach is interrupted by the attachments of the greater and lesser omenta which define the greater and lesser curvatures that separate two surfaces.

PARTS OF THE STOMACH

For descriptive purposes, the stomach is divided by arbitrary lines drawn on its external surface into a fundus, body, pyloric antrum and pylorus (Fig. 65.2). The internal appearance and microstructure of these regions varies to some degree. The fundus is dome shaped and projects above and to the left of the cardiac orifice to lie in contact with the left dome of the diaphragm. It lies above a line drawn horizontally from the incisura cardiaca to the greater curvature. The body extends from the fundus to the incisura angularis, which is a constant external notch at the lower end of the lesser curvature. A line drawn from the incisura angularis to an indentation on the greater curvature defines the lower boundary of the body. The pyloric antrum extends from this line to the sulcus intermedius, where the stomach narrows to become the pyloric canal (1–2 cm long), which terminates at the pyloric orifice.
Fig. 65.2 The parts of the stomach.
GASTRIC RELATIONS

Gastric curvatures

Lesser curvature

The lesser curvature extends between the cardiac and pyloric orifices and forms the medial (posterior and superior) border of the stomach. It descends from the medial side of the oesophagus in front of the decussating fibres of the right crus of the diaphragm, curves downwards and to the right and lies anterior to the superior border of the pancreas (Fig. 65.3). It ends at the pylorus just to the right of the midline. In the most dependent part there is typically a notch, the incisura angularis, whose position and appearance vary with gastric distension. The lesser omentum is attached to the lesser curvature and contains the right and left gastric vessels.

Greater curvature

The greater curvature is four or five times longer than the lesser. It starts from the incisura cardiaca formed between the lateral border of the abdominal oesophagus and the fundus of the stomach. It arches upwards, posterolaterally and to the left. Its highest convexity, the apex of the fundus, is approximately level with the left fifth intercostal space just below the left nipple in males, but varies with respiration. From this level it sweeps inferiorly and anteriorly, slightly convex to the left, almost as far as the tenth costal cartilage in the supine position, where it turns medially to end at the

Fig. 65.3  Posterior relations of the stomach.
pylorus. There is frequently a groove, termed the sulcus intermedius, in the curvature close to the pyloric constriction. The start of the greater curvature is covered by peritoneum which continues over the anterior surface of the stomach. Laterally the greater curvature gives attachment to the gastroplenic ligament and beyond this to the greater omentum, which contains the gastroepiploic vessels. The gastroplenic ligament and the greater omentum, together with the gastrophepnic and splenorenal ligaments, are continuous parts of the original dorsal mesogastrium: their names merely indicate regions of the same continuous sheet of peritoneum and its associated connective tissue.

**Gastric volvulus**

Volvulus of the stomach is much less common than volvulus of either the sigmoid colon or caecum. Two types of gastric volvulus may occur. The first, organoaxial volvulus, occurs about a line of rotation running from below the cardiac orifice to the pylorus. The antrum, body and fundus rotate upwards, with the greater curvature coming to lie above the lesser curvature as the volvulus progresses. The second, mesenteroaxial volvulus, occurs about a line drawn ‘across’ the body of the stomach, usually just above the incisura angularis. This type of volvulus is perpendicular to the line of organoaxial volvulus. The distal body and antrum rotate anteriorly, superiorly and laterally while the upper body and fundus rotate posteriorly, medially and inferiorly. Although relatively mobile within the upper abdomen, the stomach is normally tethered to the oesophagus at the gastro-oesophageal junction (see above), to the duodenum at the pylorus, to the spleen by the gastroplenic omentum, and to the liver by the lesser omentum. The attachment to the transverse colon via the gastrocolic omentum also restrains the stomach but is the most mobile of all. For either type of gastric volvulus to occur, it is necessary for some or all of these points of tethering to be loosened either by previous surgical division or by chronic lengthening and loosening of their connective tissue. Organoaxial volvulus is most common because the lesser omentum, gastroplenic ligament and gastrocolic omentum are more likely to undergo chronic lengthening by traction than the other attachments of the stomach. Mesenteroaxial volvulus requires the gastro-oesophageal junction and pylorus to be sufficiently mobile as to come into close approximation. These structures are firmly tethered and consequently this form of gastric volvulus is much less common. Despite the profuse gastric arterial supply, either type of volvulus may compromise the vascularity of the stomach.

**Gastric surfaces**

When the stomach is empty and contracted, the two surfaces tend to lie facing almost superiorly and inferiorly, but with increasing degrees of distension they come to face progressively more anteriorly and posteriorly (Fig. 65.4).
Fig. 65.4 Axes of the empty and full stomach. As the stomach distends, the greater curvature ‘rolls’ downwards and the anterosuperior surface comes to lie almost completely vertical as the anterior surface.

Anterior (superior) surface

The lateral part of the anterior surface is posterior to the left costal margin and in contact with the diaphragm, which separates it from the left pleura, the base of the left lung, the pericardium and the left sixth to ninth ribs (Fig. 65.5). It lies posterior to the costal attachments of the upper fibres of transversus abdominis, which separate it from the seventh to ninth costal cartilages. The upper and left part of this surface curves posterolaterally and is in contact with the gastric surface of the spleen. The right half of the anterior surface is related to the left and quadrate lobes of the liver and the anterior abdominal wall. When the stomach is empty, the transverse colon may lie adjacent to the anterior surface. The entire anterior (superior) surface is covered by peritoneum.
Posterior (inferior) surface

The posterior surface lies anterior to the left crus and lower fibres of the diaphragm, the left inferior phrenic vessels, the left suprarenal gland, the superior pole of the left kidney, the splenic artery, the anterior pancreatic surface, the splenic flexure of the colon and the upper layer of the transverse mesocolon (Fig. 65.3). Together these form the shallow stomach bed: they are separated from the stomach by the lesser sac (over which the stomach slides as it distends). The upper left part of the surface curves anterolaterally and lies in contact with the gastric surface of the spleen. The greater omentum and the transverse mesocolon separate the stomach from the duodenojejunal flexure and ileum. The posterior surface is covered by peritoneum,
except near the cardiac orifice, where a small, triangular area contacts the left diaphragmatic crus and sometimes the left suprarenal gland. The left gastric vessels reach the lesser curvature at the right extremity of this bare area in the left gastropancreatic fold. The gastrophrenic ligament passes from the lateral aspect of this bare area to the inferior surface of the diaphragm.
GASTRIC ORIFICES

Cardiac orifice and gastro-oesophageal junction

The opening from the oesophagus into the stomach is the cardiac orifice (Fig. 65.1). It is typically situated to the left of the midline behind the seventh costal cartilage at the level of the eleventh thoracic vertebra. It is typically 10 cm from the anterior abdominal wall and 40 cm from the incisor teeth. The abdominal oesophagus is continuous with the cardiac orifice; the right side is continuous with the lesser curvature, the left side with the greater curvature. There is no specific anatomically discernible cardiac sphincter related to the orifice.

Internally, the transition between oesophagus and stomach is difficult to define because mucosa of gastric fundal pattern extends a variable distance up into the abdominal oesophagus. It usually forms a ‘zig-zag’ squamo-columnar epithelial junction with the oesophageal epithelium above this Z line: for histological and endoscopic purposes, this is often referred to as the gastro-oesophageal junction. A sling of longitudinal and oblique gastric muscle fibres forms a loop on the superior, left, side of the gastro-oesophageal junction between the oesophagus and the lesser curvature, and this is taken as the external boundary of this junction. Bands of thickened circular smooth muscle in the upper wall of the greater curvature and the distal oesophagus are sometimes confusingly referred to as ‘clasp’ or ‘sphincter’ fibres.

Lower oesophageal sphincter and gastro-oesophageal reflux

At rest there is a gastro-oesophageal pressure gradient due to the presence of negative intra-thoracic pressure (transferred to the thoracic oesophagus) and positive intra-abdominal pressure (transferred to the stomach and augmented by any contraction of the stomach wall itself). Several anatomical and physiological factors normally prevent gastro-oesophageal reflux. Minor factors include the folds of gastric mucosa present in the gastro-oesophageal junction, the mucosal rosette, which contribute to the formation of a fluid- and gas-tight seal and also help to ensure that even low levels of tone within the lower oesophageal wall muscles may occlude the lumen of the junction against low pressures of gastric gas; the angle of the cardiac orifice, which is formed, in part, by the pull of the long oblique fibres of the inner layer of the gastric smooth muscle and may help to form a type of ‘flap valve’; and the length of the abdominal oesophagus, which is buttressed externally by pads of adipose connective tissue at and below the level of the diaphragmatic hiatus.

However, the major anti-reflux mechanisms are the tonic contractions of the specialized smooth muscle of the wall lower oesophageal and the encircling fibres of the right diaphragmatic crus, which, together, exert a radial pressure that can be measured by electromyography or manometric testing (Paterson 2001, Mittal 2006), and form an effective high pressure zone (HPZ). At and just below the level of the entry of the abdominal oesophagus into the stomach, the circular fibres of the intermediate layer of the muscularis externa lying over the upper lesser curvature are particularly pronounced and sometimes referred to as ‘clasp’ fibres and exert fairly constant myogenic tone (Fig. 65.6). Since the oesophagus passes obliquely into the stomach, with increasing gastric distension the tone in the clasp fibres rises and they may act to draw the anterior and posterior surfaces together, increasing the tone at the gastro-oesophageal junction, contributing to the HPZ. These anatomical and
physiological features are together referred to as the lower oesophageal sphincter (LOS). If reflux is to be prevented, the pressure within the HPZ must exceed the difference between the pressures on either side of the junction. The oesophageal part of the LOS is controlled by the intramural plexuses of the enteric nervous system via the neural release of nitric oxide which relaxes the smooth muscle of the LOS. Tone is reduced in advance of the oesophageal peristaltic wave during swallowing and raised again after the food bolus has passed. During inspiration, the greater negative intrathoracic pressure which increases the gastro-oesophageal pressure gradient is offset by increased pressure in the HPZ due to contraction of the peri-oesophageal fibres of the right diaphragmatic crus. Activation of the crural diaphragm slightly before the costal fibres ensures that this increase precedes the increase in the gradient.
Reflux of gastric contents into the abdominal and lower thoracic oesophagus as a result of transient relaxation of the LOS occurs as a normal event in most individuals for a small percentage of their daily life. It also occurs as a result of a weak LOS, or of hiatus hernia which disrupts the normal anatomical barriers. Surgical procedures to prevent excessive reflux mainly focus on the restoration of a normal length of intra-abdominal oesophagus, by reduction of any hiatus hernia which carries the gastro-oesophageal junction into the thorax, and an increase in the tonic contraction surrounding the intra-abdominal oesophagus, which is usually achieved by partial wrapping of the fundus of the stomach around the intra-abdominal oesophagus to provide greater tone, ‘fundoplication’.

**Barrett's oesophagus**

The squamous epithelium lining the lower oesophagus may be pathologically replaced by islands, strips, or circumferential patches of columnar, gastric type epithelium. This process is most likely to be the result of chronic reflux of gastric contents, acid or alkali, into the oesophagus, inducing a change in mucosal cell type. The abnormal columnar type epithelium, which may extend for a variable length up the lower part of the oesophagus, is referred to as Barrett's epithelium.

**Pyloric orifice**

The pyloric orifice is the opening from the stomach into the duodenum, and typically lies 1–2 cm to the right of the midline in the transpyloric plane when the body is supine and the stomach empty. The pyloric sphincter is a muscular ring formed by a marked thickening of the circular gastric muscle interlaced with some longitudinal fibres. The circular pyloric constriction on the surface of the stomach usually indicates the location of the pyloric sphincter, and is often marked by a prepyloric vein which crosses the anterior surface vertically downwards.
Numerous factors influence both the form and position of the stomach, including the posture and build of the individual, the extent of filling of the stomach, the position of the surrounding viscera, and the tone of the abdominal wall and gastric musculature. The empty stomach is most commonly J-shaped, the fundus usually contains gas, and, in the erect posture, the pylorus descends to the level of the second or the third lumbar vertebra. The lowest part of the antrum often lies below the level of the umbilicus, and the overall axis of the organ is slightly inclined from the vertical (Fig. 65.7). In short, obese individuals, the axis of the stomach lies more towards the horizontal as a ‘steer-horn’ shape.

Fig. 65.7 Double contrast barium meal. A, In the erect position the stomach has a more ‘J’-shaped configuration. B, Initial stomach filling demonstrates a horizontally lying stomach with prominent gastric rugal folds. C, The area gastricae within the antrum are clearly identified on distension of the stomach.
The extent of filling mainly affects the shape and position of the body, because the pyloric part usually remains contracted during digestion. As the stomach fills, it expands forwards and downwards but, when the colon or small bowel is distended, the fundus enlarges towards the liver and diaphragm. As stomach capacity increases, the pylorus is displaced to the right and the axis of the whole organ lies in a more oblique direction. In this position the anterior and posterior surfaces tend to face forwards and backwards and the lowest part is the pyloric antrum, which extends below the umbilicus. When intestinal distension interferes with downward expansion of the body, the stomach retains a horizontal position.

**Internal appearances**

During endoscopic examination (Fig. 65.8), the stomach is typically at least partially distended by air. The cardiac orifice and the lowest portion of the abdominal oesophagus viewed from above are typically closed at rest by tonic contraction of the lower oesophageal musculature. The gastric mucosa lining the orifice is puckered into ridges and is present for a short but variable distance up the abdominal oesophagus; the transition between columnar and squamous epithelium is usually clearly visible. The presence of abnormal columnar epithelium within the oesophagus is referred to as Barrett's oesophagus but the precise definition of this condition is difficult (see above). From within the distended stomach, the cardiac orifice appears in the medial wall of the fundus and is asymmetrical. The medial edge of the cardiac orifice is continuous with the medial wall of the body of the stomach. The mucosa is slightly thickened at this point with a raised profile, forming part of the 'mucosal rosette' that lines the orifice. The ‘rosette’ aids closure of the cardiac orifice and helps prevent reflux of stomach contents into the oesophagus. The medial edge of the orifice is more clearly visible than the lateral edge because it forms a more acute angle with the mucosal lining of the abdominal oesophagus.
In the partly distended stomach, the mucosa of the fundus is thrown into gentle folds with no particular pattern (rugae). As the stomach fills towards capacity, these folds rapidly become less pronounced, and the wall is nearly smooth when the stomach is over-inflated. The body of the stomach has the most pronounced mucosal folds. Even in moderate distension, they appear as long, broad mucosal ridges running in sinuous strips from fundus to pyloric antrum (Fig. 65.7). They are seen on all mucosal surfaces of the body but are most obvious on the anterolateral, lateral and posterolateral parts (which correspond to the inner surface of the anterior and posterior external surfaces and to the greater curvature). Here they are occasionally called the magenstrasse, a reference to their possible role in directing liquid entering the stomach immediately down into the pyloric antrum. These folds are least prominent on the medial surface (corresponding to the inner surface of the lesser curvature), which is much smoother, particularly when the stomach distends.

The areae gastricae within the antrum are small elevations or puckerings of the mucosal surface that are readily seen on double contrast barium meal (Fig. 65.7). The few folds present in the antrum when the stomach is relaxed disappear with distension. The antrum adjacent to the pyloric canal, the prepyloric antrum, has a smooth mucosal surface that culminates in a slight puckering of the mucosa at the pyloric orifice caused by the contraction of the pyloric sphincter.
Since the lower body and antrum of the stomach is related to the posterior aspect of the left anterior abdominal wall, it may usefully be accessed to form a gastrostomy. Its mobility enables the anterior surface of the stomach to be readily approximated to the parietal peritoneum on the posterior surface of the abdominal wall, and a communication to be established between the lumen of the stomach and the surface of the skin. Although this may be performed as a direct open surgical procedure under general anaesthetic, it is much more commonly performed using a percutaneous puncture guided by either endoscopic visualization of the stomach or radiological imaging. The procedure is made easier by the fact that the anterior surface of the stomach lies most nearly in the vertical plane when the stomach is distended. One of the main hazards of the procedure results from the occasional interposition of the transverse colon between the stomach and anterior abdominal wall, which may lead to inadvertent transfixion of the colon by the needle puncture system. The variable length of the transverse colonic mesentery means that it may sometimes lie adjacent to the anterior gastric surface when a subject is recumbent. These risks may be reduced by radiological guidance.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply to the stomach comes predominantly from the coeliac axis although intramural anastomoses exist with vessels of other origins at the two ends of the stomach (Figs 65.9, 65.10, 65.11). The left gastric artery arises directly from the coeliac axis. The splenic artery gives origin to the short gastric arteries as well as the left gastroepiploic artery and may occasionally give origin to a posterior gastric artery. The hepatic artery gives origin to the right gastric artery and to the gastroduodenal artery, which in turn gives origin to the right gastroepiploic artery.

Fig. 65.9 Arterial supply of the stomach.
Fig. 65.10 Coeliac axis and its branches. Demonstrated on digital subtraction angiography (A) and digital reformatted multislice CT angiogram (B and C). B and C by courtesy of GE Worldwide Medical Systems. (by courtesy of Dr James McCall, Chelsea & Westminster Hospital, London)
The left gastric artery is the smallest branch of the coeliac axis. It ascends to the left of the midline and crosses either just over the lower end of or below the level of the origin of the left crus of the diaphragm beneath the peritoneum of the upper posterior wall of the lesser sac. Here it lies adjacent to the left inferior phrenic artery and medial or anterior to the left suprarenal gland. It runs forwards into the superior portion of the lesser omentum adjacent to the superior end of the lesser curvature, and turns anteroinferiorly to run along the lesser curvature between the two peritoneal leaves of the lesser omentum. At the highest point of its course, it gives off one or more oesophageal branches. In its course along the lesser curvature, it gives off multiple branches that run onto the anterior and posterior surfaces of the stomach and anastomose with the right gastric artery in the region of the incisura angularis.

The left gastric artery rarely arises from the common hepatic artery or its branches. The most common of these rare variations is an origin from the left hepatic artery, when the left gastric artery passes between the peritoneal layers of the superior lesser omentum to reach the lesser curvature of the stomach. Other variants include a common origin with the common hepatic artery. (A replaced/accessory left hepatic artery origin from the left gastric artery is more common than a replaced/accessory left
gastric origin.)

Short gastric arteries

There is no universally accepted definition of what constitutes the short gastric arteries but a practical definition is ‘vessels which supply the fundus of the stomach above the level of the splenic artery and which arise to the left of the greater curvature of the stomach’. The short gastric arteries are variable in number, commonly between five and seven. They arise from the splenic artery or its divisions, or from the proximal left gastroepiploic artery, and pass between layers of the gastroepiploic ligament to supply the cardiac orifice and gastric fundus. They anastomose with branches of the left gastric and left gastroepiploic arteries. An accessory left gastric artery may arise with these vessels from the distal splenic artery.

Left gastroepiploic artery

The left gastroepiploic artery is the largest branch of the splenic artery. It arises near the splenic hilum and runs anteroinferiorly between the layers of the gastroepiploic ligament into the upper gastrocolic omentum. It lies between the layers of peritoneum close to the greater curvature, running inferiorly to anastomose with the right gastroepiploic artery. It gives off gastric branches to the fundus of the stomach through the gastroepiploic ligament, and to the body of the stomach through the gastrocolic omentum. These are necessarily longer than the gastric branches of the right gastroepiploic artery and may be 8–10 cm long. Epiploic (omental) branches arise along the course of the vessel and descend between the layers of the gastrocolic omentum into the greater omentum. A particularly large epiploic branch commonly originates close to the origin of the left gastroepiploic artery, descends in the lateral portion of the greater omentum and provides a large arterial supply to the lateral half of the omentum.

Posterior gastric artery

A distinct posterior gastric artery may occur. When present, it arises from the splenic artery in its middle section posterior to the body of the stomach (Fig. 65.11). It ascends behind the peritoneum of the lesser sac towards the fundus and reaches the posterior surface of the stomach in the gastrophrenic fold.

Right gastric artery

The right gastric artery arises from the hepatic artery as it passes forwards from the posterior wall of the lesser sac into the lower border of the lesser omentum above the first part of the duodenum. It runs between the peritoneal layers of the lesser omentum just above the medial end of the lesser curvature, passes superiorly along the lesser curvature, giving off multiple branches onto the anterior and posterior surfaces of the stomach, and anastomoses with the left gastric artery.

The origin of the right gastric artery often varies: the most common alternative origins are from the common hepatic, left hepatic, gastroduodenal or supraduodenal arteries.

Gastroduodenal artery

The gastroduodenal artery arises from the common hepatic artery posterior and
superior to the first part of the duodenum. It gives origin to the right gastroepiploic and superior pancreaticoduodenal arteries at the lower border of the first part of the duodenum. (For details of the gastroduodenal artery and its relevance to clinical situations, see Chapter 66.)

*Right gastroepiploic artery*

The right gastroepiploic artery originates from the gastroduodenal artery behind the first part of the duodenum, anterior to the head of the pancreas. It passes inferiorly towards the midline between the layers of the gastrocolic omentum, lies inferior to the pylorus, then runs laterally along the greater curvature and ends by anastomosing with the left gastroepiploic artery. It is adjacent to the pylorus but, more distally, lies approximately 2 cm from the greater curvature of the stomach. The right gastroepiploic artery gives off gastric branches that ascend onto the anterior and posterior surfaces of the antrum and lower body of the stomach, epiploic branches that descend into the greater omentum, and branches that contribute to the supply of the inferior aspect of the first part of the duodenum.

*Arterial anastomoses of the stomach*

There is an anastomosis between the oesophageal arteries originating from the thoracic aorta and the vessels that supply the fundus in the region of the cardiac orifice. At the pyloric orifice the extensive network of vessels supplying the duodenum allows for some anastomosis between vessels of superior mesenteric artery origin and the pyloric vessels. The major named vessels supplying the stomach form extensive arterial anastomoses both on the serosal surface and around the curvatures. The right and left gastroepiploic arteries and the left and right gastric arteries anastomose freely with each other along the greater and lesser curvatures respectively. Anastomoses also form between the short gastric and left gastric arteries in the region of the fundus, and between the right gastric and right gastroepiploic arteries in the region of the antrum. In addition to the extensive serosal anastomoses, networks form within the stomach wall at intramuscular, submucosal and mucosal levels. A true plexus of small arteries and arterioles is present within the submucosa: it supplies the mucosa and shows considerable regional variation both in the gastric wall and in the proximal duodenum. The rich arterial supply to the stomach ensures that the high mucosal blood flow required for physiological functioning is maintained even if one or more vessels become occluded: the stomach exhibits considerable resistance to ischaemia even when multiple arterial supplies are lost.

The pyloric arteries are rami of the right gastric and right gastroepiploic arteries. They pierce the duodenum distal to the sphincter around its entire circumference and pass through the muscular layer to the submucosa where they divide into two or three rami. The latter turn back into the pyloric canal beneath the mucosa and run to the end of the pyloric antrum: they supply the entire mucosa of the pyloric canal (Fig. 65.12). Branches of the pyloric submucosal arteries may anastomose close to their origin with the duodenal submucosal arteries, and their terminal rami also anastomose with gastric arteries from the prepyloric antrum. The pyloric sphincter is supplied by the gastric and pyloric arteries via rami that leave their parent vessels in the subserosal and submucosal levels to penetrate the sphincter.
**Dieu la Foy lesions**

Abnormalities of the intramural vascularity of the stomach are a rare cause of bleeding from the upper gastrointestinal tract. So-called 'Dieu la Foy' lesions commonly occur in the proximal body or fundus. Originally thought to be small arteriovenous malformations of the submucosal plexus, they are now considered to be caused by a...
larger than normal penetrating arterial vessel running through the muscular coat of the stomach into the submucosa before branching into the submucosal plexus.

**Veins**

The veins draining the stomach ultimately empty into the portal vein. A rich submucosal and intramural venous network gives rise to veins that usually accompany the corresponding named arteries and drain into either the splenic or superior mesenteric veins, although some pass directly into the portal vein. The course and distribution of the veins is highly variable even up to the level of the major named vessels.

**Short gastric veins**

Four or five short gastric veins drain the gastric fundus and the upper part of the greater curvature into the splenic vein or one of its large tributaries.

**Left gastroepiploic vein**

The left gastroepiploic vein drains both anterior and posterior surfaces of the body of the stomach and the adjacent greater omentum via multiple tributaries. It runs superolaterally along the greater curvature, between the layers of the gastrocolic omentum, and drains into the splenic vein within the gastrosplenic ligament.

**Right gastroepiploic vein**

The right gastroepiploic vein drains the greater omentum, distal body and antrum of the stomach. It passes medially, inferior to the greater curvature, in the upper portion of the gastrocolic omentum. Just proximal to the pyloric constriction it passes posteriorly to drain into the superior mesenteric vein below the neck of the pancreas. The right gastroepiploic vein may receive the superior pancreaticoduodenal vein close to its entry into the superior mesenteric vein.

**Left gastric vein**

The left gastric vein drains the upper body and fundus of the stomach. It ascends along the lesser curvature to the oesophageal opening where it receives several lower oesophageal veins, then curves posteriorly and medially behind the posterior peritoneal surface of the lesser sac. It drains into the portal vein directly at the level of the upper border of the first part of the duodenum.

**Right gastric vein**

The right gastric vein is typically small and runs along the medial end of the lesser curvature, passing under the peritoneum as it is reflected from the posterior aspect of the pylorus and first part of the duodenum onto the posterior wall of the lesser sac. It drains directly into the portal vein at the level of the first part of the duodenum. It receives the prepyloric vein as it ascends anterior to the pylorus at the level of the pyloric opening.

**Posterior gastric veins**

Distinct posterior gastric veins may occur, sometimes as multiple small vessels. When
present, they accompany the posterior gastric artery from the middle of the posterior surface of the stomach and drain into the splenic vein.

**Oesophageal and gastric varices**

Blood from the mucosa normally drains into a superficial venous plexus, then into a deeper intrinsic venous plexus and finally into the peri-oesophageal veins via perforating veins. In the abdominal oesophagus the perforating veins drain into tributaries of the left gastric veins; in the lower thoracic oesophagus they form tributaries of the azygos and hemiayzgos systems. Bidirectional flow is possible in this region, and accommodates pressure changes that occur during breathing and Valsalva manoeuvres.

Varices are progressive dilatations which occur predominantly in the submucosal plexus of the distal abdominal oesophagus and occasionally on the gastric side of the gastric orifice at portal venous pressures above 15 mmHg. Portal venous hypertension, of any cause, predisposes to the opening up of pre-existing embryonic venous channels between venous tributaries of the portal system and the systemic venous circulation (Paquet 2000), such as the venous plexuses which exist in the lower abdominal oesophagus and gastric orifice. In portal hypertension, the valves within the perforating vessels become incompetent, permitting retrograde flow, and this causes variceal dilatation of the deep and superficial veins. Varices in the distal oesophagus are often easily visible at endoscopy, because they are situated superficially in the lamina propria and protrude into the oesophageal lumen; they are a frequent cause of substantial upper gastrointestinal bleeding. Spontaneous cessation of the bleeding is less common than at other sites, in part because the pressure and the flow rate within the veins is high, but also because there is a relative lack of submucosal supporting connective tissue to allow for venous contraction and thrombosis. Gastric varices are often present on the inferior aspect of the gastric orifice. They present less commonly in clinical practice than oesophageal varices, are less easy to diagnose because of their location, and occasionally exist without the presence of oesophageal varices. In these circumstances, it may be that the embryonal 'point of meeting' between portal and systemic venous systems is lower than usual and occurs in the upper stomach rather than the lower oesophagus.

**Lymphatic drainage**

The stomach has a rich network of lymphatics that connect with lymphatics draining the other visceral organs of the upper abdomen. At the gastro-oesophageal junction the lymphatics are continuous with those draining the lower oesophagus, and in the region of the pylorus they are continuous with those draining the duodenum. In general, they follow the course of the arteries supplying the stomach. However, many separate groups of nodes are now recognized (Fig. 65.13), and their relationship to the regions of the stomach and the vascular territories supplied, is of great importance during resection of the stomach, particularly for malignancy. Pancreatic and hepatic lymphatics play a significant role in draining areas of the stomach during disease.

**Gastrectomy and gastric lymphadenectomy**

Surgery for gastro-oesophageal malignancy involves varying degrees of radical resection of the associated lymph nodes that potentially drain the tumour area. The wide ramification of the gastro-oesophageal lymph node drainage and the multiple
possible nodes which may be involved in a tumour inevitably mean that the extent of
lymphadenectomy undertaken may be wide. The extent of possible/actual nodal
involvement by the tumour is classified as N1 (loco-regional nodes specific to the
tumour site), N2 (regional and major named vessel nodes draining the tumour) and N3
(wider draining nodes including para-aortic nodes). Gastrectomies can be classified
according to the node groups excised for the tumour: D1 (e.g. removal of the portion
of the stomach involved and the local lymph nodes directly related to the arteries
ligated), D2 (e.g. total gastrectomy including all gastric lymph node groups often
including the spleen) and D3 (e.g. total gastrectomy plus extensive lymphadenectomy
that includes the associated upper abdominal lymph nodes, namely pancreatic,
superior mesenteric, coeliac, hepatic and transverse colic). (For details of the lymph
node stations relevant to surgical gastric resection, see Japanese Gastric Cancer
Association 1998 and UICC 1997.)
INNERVATION

The stomach is innervated by sympathetic and parasympathetic fibres.

Sympathetic innervation

The sympathetic supply to the stomach originates from the fifth to 12th thoracic spinal segments, and is mainly distributed to the stomach via the greater and lesser splanchnic nerves via the coeliac plexus. Periarterial plexuses form along the arteries and supply the stomach from the coeliac axis. Additional innervation comes from fibres of the hepatic plexus, which pass to the upper body and fundus via the upper limit of the lesser omentum and via direct branches from the greater splanchnic nerves.

The gastric sympathetic nerves are vasoconstrictor to the gastric vasculature and inhibitory to gastric musculature. The sympathetic supply to the pylorus is motor, and brings about pyloric constriction. The sympathetic supply also conducts afferent impulses that mediate sensations, including pain.

Parasympathetic innervation

The parasympathetic supply to the stomach is from the anterior and posterior vagus nerves (Fig. 65.14). The anterior vagus (formed mainly from fibres from the left vagus originating from the oesophageal plexuses) is often double or even triple and supplies filaments to the cardiac orifice. The nerve lies very closely applied to the outer muscle of the abdominal oesophagus and divides near the oesophageal end of the lesser curvature into gastric and pyloric/hepatic branches. The upper anterior gastric branches radiate on the anterior surface of the upper body and fundus. The main gastric branch is termed the greater anterior gastric nerve and lies in the lesser omentum near the lesser curvature; branches from this nerve pass to the body and antrum with the gastric arterial supply branches. Hepatic/pyloric branches (generally one main and possibly one accessory) originate below the cardiac orifice. The main hepatic/pyloric nerve runs between the peritoneal layers of the lesser omentum almost horizontally towards its free edge to reach the hilum of the liver where hepatic branches ramify and pyloric branches turn down on the left side of the hepatic artery to reach the pylorus. The second nerve usually arises from the greater anterior gastric nerve during its course and runs inferomedially to the pyloric antrum where pyloric (and antral) branches form and hepatic branches (one or two) run superiorly to contribute to the hepatic plexus. Variations in the anterior nerve include accessory pyloric branches, long gastric branches with a high lying nerve trunk and a low origin of the pyloric branch with a low lying nerve trunk.
Fig. 65.14 Distribution of the vagal nerves to the stomach. The two commonest variations in the anterior vagus are shown in pink. A, Multiple main trunks. B, Low origin of the hepatic/pyloric branch lying close to the lesser curvature.

The posterior nerve tends to lie more medial than the anterior and is often a short distance from the wall of the abdominal oesophagus. It produces two main groups of branches, gastric and coeliac. Gastric branches arise and then run behind the cardiac orifice and upper body of the stomach. They extend over the posterior surface of the body and fundus to the proximal antrum but do not normally reach the pyloric sphincter. The largest is termed the greater posterior gastric nerve and runs posteriorly along the lesser curvature. Large coeliac branches (one or more) arise from the posterior nerve as thick bundles which carry the majority of fibres forming the nerve to the coeliac plexus (and onwards). Hepatic branches (one or two) are often small and originate from the coeliac branches. No true plexus occurs on either the anterior or posterior gastric surfaces, but plexuses are present in the submucosa and between the layers of the muscularis externa.

The parasympathetic gastric supply is secretomotor to the gastric mucosa and motor to the gastric musculature. It is responsible for coordinated relaxation of the pyloric sphincter during gastric emptying.

Referred pain

The majority of the sensation of pain arising from the stomach is poorly localized, and in common with other structures of foregut origin, is referred to the central epigastrium. Pain arising from the region of the gastro-oesophageal junction is commonly referred to the lower retrosternal and subxiphoid areas.
MICROSTRUCTURE

The gastric wall consists of the major layers found elsewhere in the gut, i.e. mucosa, submucosa, muscularis externa and serosa, together with gastric vessels and nerves (Figs 65.15, 65.16). The microstructure reflects the functions of the stomach as an expandable muscular sac lined by secretory epithelium, although there are local structural and functional variations in this pattern.

Fig. 65.15 Principal regions of the interior of the stomach and the microstructure of tissues and cells within its wall. Undifferentiated, dividing cells are shown in white.
Fig. 65.16. Low power micrograph showing the stomach wall, thrown into longitudinal folds or rugae which are visible macroscopically. The surface epithelium is folded microscopically to form gastric pits. Gastric glands extend through the thickness of the mucosal lamina propria and open into the bases of the gastric pits. A muscularis mucosae layer and submucosa follow the contours of the rugae. Part of the external muscularis layers is seen below left.

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Mucosa

The mucosa is a thick layer with a soft, smooth surface that is mostly reddish brown in life but pink in the pyloric region. In the contracted stomach the mucosa is folded into numerous folds or rugae, most of which are longitudinal. They are most marked towards the pyloric end and along the greater curvature. The rugae represent large folds in the submucosal connective tissue (see below) rather than variations in the thickness of the mucosa covering them, and they are obliterated when the stomach is distended. As elsewhere in the gut, the mucosa is composed of a surface epithelium, lamina propria and muscularis mucosae.

Epithelium

When viewed microscopically at low magnification, the internal surface of the stomach wall appears honeycombed by small, irregular gastric pits approximately 0.2 mm in diameter (Figs 65.15, 65.16). The base of each gastric pit receives several long, tubular gastric glands that extend deep into the lamina propria as far as the muscularis mucosae. Simple columnar mucus-secreting epithelium covers the entire luminal surface including the gastric pits, and is composed of a continuous layer of surface mucous cells which release gastric mucus from their apical surfaces to form a thick protective, lubricant layer over the gastric lining. This epithelium commences abruptly at the cardiac orifice, where there is a sudden transition from oesophageal...
stratified squamous epithelium.

**Gastric glands**

Although all gastric glands are tubular, they vary in form and cellular composition in different parts of the stomach. They can be divided into three groups – cardiac, principal and pyloric. The most highly specialized are the principal glands.

**Principal gastric glands**

The principal glands are found in the body and fundus, three to seven opening into each gastric pit. Their junction with the base of the pit is the isthmus, immediately basal to this is the neck, and the remainder is the base. The walls of the gland contain at least five distinct cell types: chief, parietal, mucous neck, stem and neuroendocrine.

Chief (peptic) cells (Fig. 65.15) are the source of the digestive enzymes pepsin and lipase. They are usually basal in position and cuboidal in shape, and their nuclei are rounded and euchromatic. They contain secretory zymogen granules and their abundant cytoplasmic RNA renders them strongly basophilic. Parietal (oxyntic) cells are the source of gastric acid and of intrinsic factor, a glycoprotein necessary for the absorption of vitamin B\textsubscript{12}. They are large, oval and strongly eosinophilic, and have centrally placed nuclei. Parietal cells occur intermittently along the walls of the more apical half of the gland, but can reach as far as the isthmus; they bulge laterally into the surrounding connective tissue. They have a unique ultrastructure related to their ability to secrete hydrochloric acid. The luminal side of the cell is deeply invaginated to form a series of blind-ended channels (canaliculi) that bear numerous irregular microvilli covered by a plasma membrane rich in H\textsuperscript{+}/K\textsuperscript{+} ATPase antiporter channels. The latter actively secrete hydrogen ions into the lumen; chloride ions follow along the electrochemical gradient. The mitochondria-rich cytoplasm facing these channels contains a tubulo-vesicular system of abundant fine membranous tubules directed towards the canalicular surface. The precise structure of the cell varies with its secretory phase: when stimulated, the number and surface area of the microvilli increases up to five-fold, probably as a result of the rapid fusion of the tubulo-vesicular system with the plasma membrane. This process is reversed at the end of stimulated secretion, when the excess membrane retreats back into the tubulo-alveolar system and microvilli are lost.

Mucous neck cells are numerous at the necks of the glands and are scattered along the walls of the more basal regions. They are typical mucus-secreting cells, displaying apical secretory vesicles containing mucins, and basally displaced nuclei: their products are distinct histochemically from those of the superficial mucous cells.

Stem cells are relatively undifferentiated mitotic cells from which the other types of gland cell are derived. They are relatively few in number, and are situated in the isthmus of the gland and the bases of the gastric pits. Stem cells are columnar and possess a few short apical microvilli. They periodically undergo mitosis; their progeny migrate either apically, to differentiate into new surface mucous cells, or basally, to form mucous neck, parietal, chief or neuroendocrine cells. All of these cells have a limited lifespan, especially the mucus-secreting types, and so they are constantly replaced. The typical replacement period for surface mucous cells is 3 days, and for mucous neck cells is 1 week. Other cell types appear to live much longer.
Neuroendocrine (enteroendocrine) cells occur in all types of gastric gland, but more frequently in the body and fundus of the stomach. They are situated mainly in the deeper parts of the glands, among the chief cells. They are basally situated, pleomorphic cells and display irregular nuclei surrounded by granular cytoplasm that contains clusters of large (0.3 µm) secretory granules. Neuroendocrine cells synthesize a number of biogenic amines and polypeptides that are important in the control of gut motility and glandular secretion. They are part of the system of dispersed neuroendocrine cells: in the stomach they include G cells, which secrete gastrin; D cells, which secrete somatostatin; and ECL (enterochromaffin-like) cells, which secrete histamine.

Cardiac glands

Cardiac glands are confined to a small area near the cardiac orifice: some are simple tubular glands, others are compound branched tubular. Mucus-secreting cells predominate; parietal and chief cells are present, but sparse.

Pyloric glands

Pyloric glands empty via groups of two or three short convoluted tubes into the bases of the deep gastric pits of the pyloric antrum: the pits occupy about two-thirds of the mucosal depth (Fig. 65.17). The glands are populated mainly by mucus-secreting cells, but they also contain neuroendocrine cells, especially G cells, which secrete gastrin when activated by appropriate mechanical stimulation (causing increased gastric motility and secretion of gastric juices). Although parietal and chief cells are scarce, parietal cells are always present in both fetal and postnatal pyloric glands, and may also appear in the duodenal mucosa, proximally near the pylorus, in adult tissue.
Fig. 65.17 Micrograph showing the pyloric region of the stomach. Pyloric glands are stained with the periodic acid-Schiff (PAS) technique to show mucin (magenta) in the gastric pits and glands. Pale staining cells are the larger parietal cells (P) and smaller enteroendocrine cells (E).

_Lamina propria_

The lamina propria forms a connective tissue framework between the glands. It contains small masses of lymphoid tissue, gastric lymphatic follicles, which resemble solitary intestinal follicles (especially in early life). It also contains a complex periglandular vascular plexus involved in the maintenance of the mucosal environment, e.g. the removal of bicarbonate produced in the tissues as a counterpart to acid secretion, and neural plexuses rich in both sensory and motor terminals.
Muscularis mucosae

The muscularis mucosae is a thin layer of smooth muscle fibres lying external to the layer of glands, arranged as continuous inner circular and outer longitudinal layers, and a discontinuous external circular layer. The inner layer sends strands of smooth muscle cells between the glands: their contraction probably assists in emptying into the gastric pits.

Submucosa

The submucosa is a variable layer of loose connective tissue. It contains thick bundles of collagen, numerous elastin fibres, blood vessels and nervous plexuses, including the ganglionated submucosal (Meissner's) plexus.

Muscularis externa

The muscularis externa is a thick muscle coat immediately under the serosa, with which it is closely connected by subserous loose connective tissue. From innermost outwards, it contains oblique, circular and longitudinal layers of smooth muscle fibres. The layers are not always easily separated: the circular layer is poorly developed in the oesophageal region, but is thickened at the distal pyloric antrum to form the anular pyloric sphincter; the outer longitudinal layer is most pronounced in the upper two-thirds of the stomach; the inner oblique layer is most obvious in the lower half.

The actions of the muscularis externa of the stomach produce a churning movement that mixes food with the gastric secretions. When the muscles contract, they reduce the volume of the stomach and throw the mucosa into longitudinal folds or rugae (see above). The folds flatten as the stomach distends with food and the musculature relaxes and thins. Muscle activity is controlled by a network of unmyelinated autonomic nerve fibres and their ganglia which lie between the muscle layers in the myenteric (Auerbach's) plexus.

Serosa or visceral peritoneum

The serosa is an extension of the visceral peritoneum. It covers the entire surface of the stomach other than along the attachments of the greater and lesser omenta to the greater and lesser curvatures respectively, where the peritoneal layers are separated by vessels and nerves, and over a small posteroinferior area near the cardiac orifice, where the stomach contacts the diaphragm at the reflections of the gastrophrenic and left gastropancreatic folds.

CHAPTER 66 – Small intestine

OVERVIEW

The small intestine consists of the duodenum, jejunum and ileum. It extends from the distal end of the pyloric canal to the ileocaecal valve, an overall length of 5 metres (3–7 metres) in the living adult. The duodenum extends up to the duodenojejunal junction, and the remaining small intestine is often referred to as the 'small bowel', of which the proximal two-fifths is referred to as the jejunum and the distal three-fifths as the ileum. There is no clear distinction between the two parts, but there is a gradual change in morphology from the proximal to distal ends of the small bowel. The distal 30 cm or so of the ileum is often referred to as the terminal ileum, which has some specialized physiological functions.

The duodenum lies mostly in the upper retroperitoneum. The jejunum and ileum occupy the central and lower parts of the abdominal cavity and usually lie within the boundary formed by the abdominal colon; they are attached to the posterior abdominal wall by a mesentery which allows considerable mobility of the loops of small bowel. In the supine position, loops of jejunum may be found anterior to the transverse colon, stomach and even lesser omentum, whereas in the upright position, loops of ileum may descend into the pelvis anterior to the rectum and, in women, may occupy the rectouterine pouch. The upper jejunum and some ileum are often covered anteriorly by the greater omentum. The jejunum and ileum are covered by peritoneum on all but their mesenteric borders, here the adipose connective tissue of the mesentery abuts the muscular wall. The serosal peritoneum is continuous with the peritoneum enclosing the tissues of the mesentery. Mesenteric fat covers 20% of the circumference wall of the ileum and somewhat less of the jejunum.
DUODENUM

The adult duodenum is 20–25 cm long and is the shortest, widest and most predictably placed part of the small intestine. It is only partially covered by peritoneum, although the extent of the peritoneal covering varies along its length: the proximal 2.5 cm is intraperitoneal, and the remainder is retroperitoneal. The duodenum forms an elongated ‘C’ that lies between the level of the first and third lumbar vertebrae in the supine position. The lower ‘limb’ of the C extends further to the left of the midline than the upper limb. The head and uncinate process of the pancreas lie within the concavity of the duodenum which is ‘draped’ over the prominence formed from the lumbar spine, the duodenum therefore bends in an antero-posterior direction as well as following the form of a ‘C’. The duodenum lies entirely above the level of the umbilicus and is described as having four parts (Figs 66.1, 66.2).

Fig. 66.1 A, The four parts of the duodenum. B&C, The relations of the duodenum: B, anterior surface; C, posterior surface.
FIRST (SUPERIOR) PART

The first, and most mobile, part of the duodenum is about 5 cm long. It starts as a continuation of the duodenal end of the pylorus and ends at the superior duodenal flexure. Peritoneum covers the anterior and superior part of its posterior aspect close to the pylorus, where the duodenum forms part of the anterior wall of the epiploic foramen. Here the lesser omentum is attached to its upper border and the greater omentum to its lower border. The first 2 or 3 cm have a bland internal mucosal appearance and readily distend on insufflation during endoscopy. This part is
frequently referred to as the duodenal ‘cap’. It has a triangular, homogeneous appearance during contrast radiology, shows the same pattern of internal rugae as the pylorus, and is often visible on plain radiographs of the abdomen as an isolated triangular gas shadow to the right of the first or second lumbar vertebra. The duodenum next passes superiorly, posteriorly and laterally for 5 cm before curving sharply inferiorly into the superior duodenal flexure: it rapidly becomes more retroperitoneal during this part of its course, until peritoneum only covers its anterior aspect. From the end of the duodenal cap, its internal appearance is characterized by extensive, deep mucosal folds that involve up to half of the circumference of the lumen. Even during endoscopic insufflation, these folds are pronounced (Fig. 66.3) and they are readily seen on contrast radiographs. The section from the duodenal cap to the superior duodenal flexure lies posterior and inferior to the quadrate lobe of the liver.

Fig. 66.3  Endoscopic appearance of the duodenum: A, Duodenal cap (first part). B, Second part showing the pronounced, ‘branched’ mucosal folds. C, Major duodenal papilla. D, Third part.

The first part of the duodenum lies anterior to the gastroduodenal artery, common bile duct and portal vein and anterosuperior to the head and neck of the pancreas. It is posterior to the neck of the gallbladder. The gastroduodenal artery lies immediately posterior to the posterior wall of the duodenum: penetrating peptic ulceration in the posterior wall and subsequent erosion of the gastroduodenal artery may lead to dramatic haemorrhage. Penetrating peptic ulceration in the anterior wall may lead to
free perforation into the peritoneal cavity because the anterior surface of the first part is covered only by peritoneum.

The common hepatic and hepatoduodenal lymph nodes lie close to the first part of the duodenum and can be visualized using endoscopic ultrasound. This may be important in the staging of gastric, pancreatic or bile duct tumours. The proximity of the common bile duct to the first part of the duodenum allows endoscopic ultrasound examination of the distal common bile duct and the formation of a surgical anastomosis between bile duct and duodenum (choledochoduodenostomy) when required.

The junction of the first and second parts of the duodenum lies posterior to the neck of the gallbladder.
SECOND (DESCENDING) PART

The second part of the duodenum is 8–10 cm long. It starts at the superior duodenal flexure and runs inferiorly in a gentle curve, convex to the right side of the vertebral column and extending to the lower border of the third lumbar vertebral body. It then turns sharply medially into the inferior duodenal flexure which marks its junction with the third part of the duodenum. It is covered by peritoneum only on its upper anterior surface, lies posterior to the neck of the gallbladder and the right lobe of the liver at its start, and is crossed anteriorly by the transverse colon. The medial end of the gastrocolic omentum and the origin of the transverse mesocolon are attached to the anterior surface of the duodenum by loose connective tissue. Below the attachment of the transverse mesocolon, the connective tissue and vessels forming the mesentery of the upper ascending colon and hepatic flexure are loosely attached to its anterior surface. This section of duodenum is at risk of injury during surgical mobilization of the ascending colon.

The second part lies anterior to the hilum of the right kidney, the right renal vessels, the edge of the inferior vena cava and the right psoas major. The head of the pancreas and the common bile duct are medial and the hepatic flexure is above and lateral. A small part of the pancreatic head is sometimes embedded in the medial duodenal wall, and pancreatic ‘rests’ in the duodenal wall may produce small filling defects on contrast radiology. The internal appearance is similar to that of the distal portion of the first part of the duodenum, with pronounced mucosal folds (Fig. 66.3). The common bile duct and pancreatic duct enter the medial wall obliquely and usually unite to form the common hepatopancreatic ampulla. The narrow distal end opens on the summit of the major duodenal papilla (ampulla of Vater), which is situated on the posteromedial wall of the second part, 8–10 cm distal to the pylorus. There are variants of the ductal anatomy. The most common is a second, accessory pancreatic duct which may open 2 cm above the major papilla on a minor duodenal papilla. Peptic ulceration of the second part of the duodenum is less common than that of the first part, and tends to occur on the anterior or lateral wall.

Duodenal diverticula

The duodenum is the most common site for a diverticulum in the small intestine. Diverticula are congenital and usually solitary. They almost always arise in the medial wall of the second part of the duodenum, intimately related to the head of the pancreas, such that the major duodenal papilla may frequently be found either on the mucosal fold at the mouth of a diverticulum or arising from the mucosa within the body of a diverticulum, particularly on the superomedial wall. This may complicate interpretation of contrast radiographs of the duodenum or biliary system, and may cause difficulties during attempted endoscopic cannulation of the papilla because
the diverticulum may restrict access. If the papilla is located on or close to the anterior wall of a diverticulum, the procedure of opening the ampulla with an electrocautery current during attempted cannulation (sphincterotomy) is made more hazardous because the wall is thin at this point and so there is a risk of free perforation into the peritoneal cavity.
THIRD (HORIZONTAL) PART

The third part of the duodenum starts at the inferior duodenal flexure and is approximately 10 cm long. It runs from the right side of the lower border of the third lumbar vertebra, angled slightly superiorly, across to the left, anterior to the inferior vena cava, becoming continuous with the fourth part in front of the abdominal aorta. It lies posterior to the transverse mesocolon, the origin of the small bowel mesentery and the superior mesenteric vessels. The lower portion of its anterior aspect is covered by peritoneum which is reflected anteriorly to form the posterior layer of the origin of the small bowel mesentery. The anterior surface of the left lateral end, close to the junction with the fourth part, is also covered with peritoneum.

The third part is anterior to the right ureter, right psoas major, right gonadal vessels, inferior vena cava and abdominal aorta (at the origin of the inferior mesenteric artery), and inferior to the head of the pancreas. Anteroinferiorly, loops of jejunum lie in the right and left infracolic compartments. The mid portion of the third part lies in the angle between the superior mesenteric vessels, just below their origin, anteriorly, and the abdominal aorta posteriorly: very rarely, this arrangement is associated with intermittent symptoms of obstruction of the duodenum at this point.
FOURTH (ASCENDING) PART

The fourth part of the duodenum is 2.5 cm long. It starts just to the left of the aorta, runs superiorly and laterally to the level of the upper border of the second lumbar vertebra, then turns sharply anteroinferiorly at the duodenojejunal flexure to become continuous with the jejunum. The main trunk of the inferior mesenteric vein lies either posterior to the duodenojejunal flexure or beneath the adjacent peritoneal fold. (The duodenojejunal flexure is a useful landmark to locate the vein radiologically or surgically.) The aorta, left sympathetic trunk, left psoas major, left renal and left gonadal vessels are all posterior relations, the left kidney and left ureter are posterolateral, and the upper part of the root of the small bowel mesentery, the left lateral transverse mesocolon and transverse colon, which separate it from the stomach, are anterior. The peritoneum of the root of the small bowel mesentery continues over its anterior surface. The lower border of the body of the pancreas is superior.

At its left lateral end, the fourth part becomes progressively covered in peritoneum on its superior and inferior surfaces, such that it is suspended from the retroperitoneum by a double fold of peritoneum, the ligament of Treitz, at the start of the duodenojejunal flexure. The ligament of Treitz may contain a small slip of muscle, the suspensory muscle of the duodenum. When present, the suspensory muscle contains skeletal muscle fibres that run from the left crus of the diaphragm to connective tissue around the coeliac axis, and smooth muscle fibres that run from the coeliac axis: its function is unknown. It is an important landmark in the radiological diagnosis of incomplete rotation and malrotation of the small intestine (see Ch. 73). The ligament of Treitz does not form part of the duodenal mesentery because the vascular supply to the fourth part of the duodenum continues to enter its wall from the posteromedial aspect.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The main vessels supplying the duodenum are the superior and inferior pancreaticoduodenal arteries. The first and second parts also receive contributions from several sources including the right gastric, supraduodenal, right gastroepiploic, hepatic and gastroduodenal arteries. Branches of the superior pancreaticoduodenal artery may contribute to the supply of the pyloric canal, with a minor degree of anastomosis to the gastric arteries in the muscular layer across the pyloroduodenal junction (Fig. 66.4).

Fig. 66.4 The arterial supply of the duodenum. Only representative branches of the small vessels, which may be multiple, are shown.

Gastroduodenal artery
The gastroduodenal artery usually arises from the common hepatic artery behind, or sometimes above, the first part of the duodenum. It descends between the first part of the duodenum and the neck of the pancreas, immediately to the right of the peritoneal reflection from the posterior surface of the duodenum. It usually lies to the left of the common bile duct but occasionally is anterior. At the lower border of the first part of the duodenum it divides into the right gastroepiploic and superior pancreaticoduodenal arteries. Before its division, the lowest part of the artery gives rise to small branches that supply the pyloric end of the stomach and the pancreas, and retroduodenal branches that supply the first part and the proximal portion of the second part of the duodenum directly. Although the gastroduodenal artery usually branches from the common hepatic artery, it may also arise as a trifurcation with the right and left hepatic arteries, or from the superior mesenteric artery or the left hepatic artery (occasionally), or from the coeliac axis or right hepatic artery (rarely).

The supraduodenal artery often arises from the gastroduodenal artery behind the upper border of the first part of the duodenum and supplies the superior aspect of the first part; it may occasionally arise from the common hepatic artery or right gastric artery. Because of its close relationship to the posteromedial wall of the second part of the duodenum, deeply penetrating ulcers or tumours of the duodenum may cause torrential bleeding from the gastroduodenal ‘artery of haemorrhage’, not least because of the profuse arterial network in the region ensures a high flow rate in the vessel.

### Superior pancreaticoduodenal arteries

The superior pancreaticoduodenal artery is usually double. The anterior artery is a terminal branch of the gastroduodenal artery and descends in the anterior groove between the second part of the duodenum and the head of the pancreas. It supplies branches to the first and second parts of the duodenum and to the head of the pancreas, and anastomoses with the anterior division of the inferior pancreaticoduodenal artery. The posterior artery is usually a separate branch of the gastroduodenal artery and is given off at the upper border of the first part of the duodenum. It descends to the right, anterior to the portal vein and common bile duct as the latter lies behind the first part of the duodenum. It then runs behind the head of the pancreas, crosses posterior to the common bile duct (which is embedded in the head of the pancreas), enters the duodenal wall and anastomoses with the posterior division of the inferior pancreaticoduodenal artery. The posterior artery supplies branches to the head of the pancreas, the first and second parts of the duodenum, and several branches to the lowest part of the common bile duct.

### Inferior pancreaticoduodenal artery

The inferior pancreaticoduodenal artery usually arises from the superior mesenteric artery or its first jejunal branch, near the superior border of the third part of the duodenum. It crosses behind the superior mesenteric vein and divides directly into anterior and posterior branches. The anterior branch passes to the right, anterior to the lower border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery. The posterior branch runs posteriorly and superiorly to the right, lying posterior to the lower border of the head of the pancreas, and anastomoses with the posterior superior pancreaticoduodenal artery. Both branches supply the pancreatic head, its uncinate process and the second and third parts of the duodenum. Occasionally the anterior and posterior
branches arise separately from the superior mesenteric or first jejunal artery.

**Jejunal artery branches**

Branches from the first jejunal branch of the superior mesenteric artery supply the fourth part of the duodenum and frequently form an anastomosis with the terminal branch of the anterior inferior pancreaticoduodenal artery (which arises from the superior mesenteric artery). The fourth part of the duodenum therefore receives a potential collateral supply from the coeliac axis and superior mesenteric artery, which means that it is not commonly affected by ischaemia.

**Veins**

The duodenal veins drain ultimately into the portal vein. Submucosal and intramural veins give rise to pancreaticoduodenal veins that usually accompany the corresponding named arteries. The superior pancreaticoduodenal vein is formed medial to the mid point of the second part of the duodenum. It runs superomedially on the posterior surface of the head of the pancreas, passes posterior to the distal common bile duct and drains into the portal vein behind the neck of the pancreas. The inferior pancreaticoduodenal vein runs from the anteromedial aspect of the second part of the duodenum inferiorly in the groove between the second and third parts of the duodenum and the head of the pancreas. It usually drains into the superior mesenteric vein but may drain into the right gastroepiploic vein. Small veins from the first and upper second part of the duodenum may drain into the prepyloric vein and veins from the third and fourth parts may drain directly into the superior mesenteric vein.

**Lymphatics**

Duodenal lymphatics run to anterior and posterior pancreatic nodes that lie in the anterior and posterior grooves between the head of the pancreas and the duodenum: these nodes drain widely into the supra-pyloric, infrapyloric, hepatoduodenal, common hepatic and superior mesenteric nodes.
INNERVATION

The duodenum is innervated by both parasympathetic and sympathetic neurones.

Preganglionic sympathetic axons originate from neurones in the intermediolateral columns of the grey matter in the fifth to the 12th thoracic spinal segments. They travel via the greater and lesser splanchnic nerves to the coeliac plexus where they synapse on neurones in the coeliac ganglion: postganglionic axons are distributed to the duodenal wall via periarterial plexuses on the branches of the coeliac axis and superior mesenteric artery. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

The preganglionic parasympathetic supply is carried by vagal axons that are distributed via the coeliac plexus and which synapse on neurones in the duodenal wall. The parasympathetic supply is secretomotor to the duodenal mucosa and motor to the duodenal musculature. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

Referred pain

In common with other structures derived from the foregut, the visceral sensation of pain arising from the duodenum is poorly localized and referred to the central epigastrium.
JEJUNUM

The jejunum has a median external diameter of 4 cm and an internal diameter of 2.5 cm. It has a thicker wall than the ileum, and an extensive arterial blood supply that makes it appear redder than the ileum in the living. The plicae circulares are most pronounced in the proximal jejunum, where they are more numerous and deeper than elsewhere in the small bowel (Fig. 66.5A). They frequently ‘branch’ around the lumen and may appear to be ranged one on top of another, giving the jejunum a characteristic appearance during single contrast radiography (Fig. 66.6). Lymphoid aggregates are almost absent from the proximal jejunum, but are present distally, although they are fewer in number and smaller than in the ileum. Where present, they are usually discoid in shape and impalpable.

![Figure 66.5](image-url)  
**Fig. 66.5** Typical cross sections through the proximal jejunum (A) and terminal ileum (B). The mesenteric attachment is wider in the jejunum, and two leaves of vessels enter the bowel wall. The latter is also thicker in the jejunum.
In the supine position the jejunum usually occupies the upper left infracolic compartment, extending down to the umbilical region. The first one or two loops often occupy a recess between the left part of the transverse mesocolon and the left kidney. On supine radiological examination, the jejunal loops are characteristically situated in the upper abdomen, to the left of the midline, whereas the ileal loops tend to lie in the lower right part of the abdomen and pelvis. This distribution can be reversed during paralytic ileus or small bowel obstruction due to rotation around the mesenteric attachment following bowel distension.

Jejunal feeding
In situations where the stomach and duodenum are either unsuitable or unavailable for receiving oral nutrition, delivery of prepared feed to the jejunum is possible using either a surgically created jejunostomy or by insertion of a feeding tube. Because the jejunum is highly mobile, it is possible to bring the first or second loop of jejunum into contact with the abdominal wall to create a surgical jejunostomy. Insertion of a fine-bore feeding tube via the nose as far as the jejunum is also possible: the end of the feeding tube must lie beyond the duodenojejunal flexure to prevent reflux of the feed into the duodenum and stomach, and this is usually confirmed by radiological monitoring of the progress of the tube through the duodenum.
ILEUM

The ileum has a median external diameter of 3.5 cm and an internal diameter of 2 cm, and tends to have a thinner wall than the jejunum (Fig. 66.5B). The plicae circulares become progressively less obvious in the distal mucosa in the ileum; they tend to be single and flatter with less pronounced crests (Figs 66.6, 66.7), and the mucosa of the terminal ileum immediately proximal to the ileocaecal valve may appear almost flat. Lymphoid aggregates are larger and more numerous than in the jejunum and may be easily palpable in the terminal ileum. They are most prominent in early childhood and, when enlarged in viral infections, may form the apex of an ileo-ileal intussusception. They become less prominent prior to puberty, and attain adult morphology by late teenage years. In the supine position, the ileum lies mainly in the hypogastric region and right iliac fossa. The terminal ileum frequently lies in the pelvis, whence it ascends over the right psoas major and right iliac vessels, to end by opening into the ileocaecal valve in the right iliac fossa.

**Fig. 66.7** Endoscopic appearance of the terminal ileum.

Meckel's diverticulum

An ileal diverticulum (of Meckel) exists in 3% of adults and represents the remnant of the proximal part of the intestino-vitelline duct. It projects from the antimesenteric border of the terminal ileum and is commonly located between 50 and 100 cm from
the ileocaecal valve. It is variable in length (median 5 cm), often possessing a short ‘mesentery’ of adipose tissue that extends from the ileal mesentery up to its base. The lumen of the diverticulum usually has a calibre similar to that of the ileum. The tip is normally free but occasionally it may be connected to the anterior abdominal wall near the umbilicus by a fibrous band. The mucosa is typically ileal, but small heterotopic areas of gastric body type epithelium, pancreatic, colonic or other tissues may also occur in the wall of a diverticulum. Unopposed acid secretion by heterotopic gastric body type epithelium may occasionally give rise to bleeding in the adjacent normal ileal mucosa. Diverticular inflammation may mimic acute appendicitis; since Meckel's diverticulum and the appendix are both derived from midgut structures, pain from either structure is referred to the periumbilical region.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Branches from the superior mesenteric artery supply the jejunum and ileum. The arteries divide as they approach the mesenteric border, giving off numerous branches which extend between the serosal and muscular layers, supplying the muscle and forming an intricate sub-mucosal plexus that supplies the glands and villi. Although there is a profuse anastomotic network of arteries within the mesentery, anastomoses between the terminal branches close to the intestinal wall are few (Fig. 66.8). The intramural and submucosal arterial networks are not of large calibre, which means that flow along lengths of small bowel is limited to a few centimetres, and division or occlusion of several consecutive vasa recta may produce segmental, focal ischaemia. Division of more proximal vessels allows flow to continue in the arcades for moderately long lengths of intestine.

![Specimens of the jejunum (A) and ileum (B) from a cadaver where the superior mesenteric artery was injected with a red coloured mass of gelatin before fixation. Subsequently the specimens were dehydrated and then cleared in benzene followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1–3) in the jejunum, becoming more numerous (5–6) in the ileum. From the arcades, straight arteries pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vascularity of the jejunal wall.](Specimens prepared by MCE Hutchinson; photographs by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)

Superior mesenteric artery

The superior mesenteric artery originates from the aorta 1 cm below the coeliac trunk, at the level of the intervertebral disk between the first and second lumbar vertebrae (Figs 66.9, 66.10). The angle of its origin from the aorta is acute, which makes cannulation via the transfemoral route somewhat difficult. The artery runs inferiorly and anteriorly, anterior to the uncinate process of the pancreas and the third part of
the duodenum, and posterior to the splenic vein and the body of the pancreas. The left renal vein lies behind it and separates it from the aorta (Fig. 66.11). The artery crosses anterior to the inferior vena cava, right ureter and right psoas major as it descends in the root of the small bowel mesentery. Its calibre progressively decreases as successive branches are given off to loops of jejunum and ileum, and its terminal branch anastomoses with the ileocolic artery.

Fig. 66.9 The superior mesenteric artery and its branches. The outlines of representative ileal and jejunal loops, appendix, caecum, ascending and transverse colon are shown for reference. Only the origin of jejunal and ileal branches are shown. For details of arcades see Fig. 66.8.

(by courtesy of Dr Adam Mitchell, Charing Cross Hospital, London). **B**, Surface shaded, volume rendered CT angiogram (by courtesy of Dr Nasir Khan, Chelsea and Westminster Hospital, London) (by courtesy of GE Worldwide Medical Systems)
The superior mesenteric artery gives off middle colic, right colic (sometimes), ileocolic, jejunal and ileal branches. It may be the source of the common hepatic, gastroduodenal, accessory right hepatic, accessory pancreatic or splenic arteries, and may arise from a common coeliacomesenteric trunk. Its jejunal and ileal branches form arcades within the mesentery to a varying extent. The last of these arcades is said to form a ‘ marginal artery’ of the small intestine, although the latter is irregular and not a single definable vessel. Straight arteries, the vasa recta, which supply the small intestine directly without further branches, are given off from this lowest arcade.

The remnant of the vitellointestinal artery (the embryonic artery which originally connected the intestinal circulation to the yolk sac) is usually obliterated; when present, it forms the artery supplying a Meckel’s diverticulum. It is occasionally represented in the mesentery by a fibrous strand from the region of the last ileal branch.

Jejunal branches

There are usually five to ten jejunal branches which arise from the left side of the upper portion of the superior mesenteric artery (Figs 66.9, 66.10). They are distributed to the jejunum as a series of short arcades which form a single (occasionally double) tier of anastomotic arcs before giving rise to multiple vasa recta (Fig. 66.8). These vessels run almost parallel in the mesentery and are distributed alternately to opposite
aspects of its wall where the two series of vessels form distinct ‘leaves’ within the mesentery. Small twigs supply regional lymph nodes and other structures in the mesentery.

Ileal branches

Ileal branches are more numerous than the jejunal branches but smaller in calibre. They arise from the left and anterior aspects of the superior mesenteric artery. The length of the mesentery is greater in the ileum and the branches form three, four or sometimes five tiers of arcs within the mesentery before giving rise to multiple vasa recta that run directly towards the ileal wall. The ileal branches run parallel in the mesentery and are distributed to alternate aspects of the ileum. They are longer and smaller than similar jejunal vessels, particularly in the distal ileum, and do not form such definite parallel ‘leaves’ of vessels. The vascular supply in the last loop of the terminal ileum is limited. There are usually only two separate arcades, peri-serosal and in the mid-zone of the mesentery. They each receive a contribution from the ileal branch of the ileocolic artery and the last ileal branch of the superior mesenteric artery and are often larger in calibre than the mid-ileal vessels. Other than this connection, few if any vessels connect the ileocolic and superior mesenteric arteries, which makes surgical exposure of the ileocolic artery up to its origin relatively simple.

Veins

Superior mesenteric vein

The superior mesenteric vein drains the small intestine, caecum, ascending and transverse parts of the colon (Fig. 66.12; see Fig. 60.8). It is formed in the right lower mesentery of the small bowel by the union of tributaries from the terminal ileum, caecum and vermiform appendix. It ascends in the mesentery to the right of the superior mesenteric artery, passes anterior to the right ureter, inferior vena cava, third part of the duodenum and uncinate process of the pancreas, and finally joins the splenic vein behind the neck of the pancreas to form the portal vein.
Tributaries

The superior mesenteric vein receives jejunal, ileal, ileocolic, right colic (when present), middle colic, right gastroepiploic and pancreaticoduodenal veins in a similar distribution to the corresponding arteries.

Lymphatics

Lymph vessels, lacteals, are found in the mucosa and muscular coat of the small bowel. Lacteals from the villi arise from an intricate plexus in the mucosa and submucosa and are joined by vessels from lymph spaces at the bases of solitary lymphoid follicles. They drain to larger vessels at the mesenteric border of the gut.
The lacteals of the muscular tunic form a close plexus that runs mostly between the two muscle layers; they communicate freely with mucosal vessels and open into vessels at the mesenteric border. Mesenteric lacteals pass between the layers of the mesentery and drain into a series of mesenteric lymph nodes which are arranged in tiers within the mesentery and which follow the same distribution as the regional arterial supply; they may form ‘chains’ along the major arteries. Elsewhere in the ileal and jejunal mesenteries the lacteals form an extensive network that affords a relatively wide field of lymph node drainage. This arrangement makes radical surgical resection of lymph nodes difficult if the vessels to the remaining unaffected small bowel are to be preserved. The mesenteric nodes drain into superior mesenteric nodes around the root of the superior mesenteric artery.
INNERVATION

The ileum and jejunum are innervated by parasympathetic and sympathetic fibres via the superior mesenteric plexus (see Figs 60.2–60.4). Preganglionic sympathetic axons originate from neurones in the intermediolateral grey matter of the mid-thoracic spinal segments and travel in the greater and lesser splanchnic nerves to the superior mesenteric ganglion where they synapse. Postganglionic axons accompany the superior mesenteric artery into the mesentery and are distributed along branches of the artery. The sympathetic nerves are vasoconstrictor to the vasculature and inhibitory to the musculature of the jejunum and ileum.

Preganglionic parasympathetic axons travel in the anterior and right vagus nerve and are secretomotor to the mucosa and motor to the musculature of the jejunum and ileum.

Referred pain

In common with other structures derived from the midgut, the visceral sensation of pain arising from the jejunum or ileum is poorly localized, and is usually referred to the periumbilical region or central epigastrium.
MICROSTRUCTURE

The intestinal wall is composed of mucosa, submucosa, muscularis externa and serosa or adventitia. The mucosa is thick and very vascular in the proximal small intestine, but thinner and less vascular distally. In places it is ridged by the underlying submucosa to form circular folds, plicae circulares, which protrude into the lumen; mucosal finger- or leaf-like intestinal villi cover the whole surface (Fig. 66.13). There are numerous simple tubular intestinal glands or crypts between the bases of the villi, and additional submucosal glands in the duodenum. The submucosa contains aggregates of lymphoid tissue, most numerous in the ileum.

![Circular folds](image)

**Fig. 66.13** Internal aspect of a representative sample of the proximal jejunum, showing circular folds.

**Circular folds**

Other than in the first part of the duodenum, large crescentic folds of mucosa project into the lumen of the small intestine, lying either transversely or slightly obliquely to its long axis (Fig. 66.14). Unlike gastric folds they are not lost during physiological distension of the intestine. Most extend round half or two-thirds of the luminal circumference, some are complete circles, some bifurcate and join adjacent folds, yet others are spiral but extend only once (occasionally two or three times) round the lumen. Larger folds are up to 8 mm deep at their broadest, but most are smaller than this, and larger folds often alternate with smaller ones. Folds begin to appear 2.5–5 cm beyond the pylorus. Distal to the major duodenal papilla they are large and close together, as they also are in the proximal half of the jejunum. From here to midway
along the ileum they diminish, and they disappear almost completely in the distal ileum, which accounts for the thinness of this part of the intestinal wall. The circular folds slow the passage of the intestinal contents and increase the absorptive surface. They are visible in contrast and occasionally plain radiographs.

![Image of intestinal folds](image)

**Fig. 66.14** Low-power micrograph showing several circular folds in the wall of the ileum. The folds are covered with villi projecting into the lumen and the submucosa extends into the core of each fold. Circular (innermost) and longitudinal smooth muscle layers form the underlying muscularis externa. Large masses of lymphoid tissue (Peyer's patches) occupy the mucosa at the left of the field.

*(By permission from Young B, Heath JW 2000 Wheater’s Functional Histology. Edinburgh: Churchill Livingstone.)*

**Intestinal villi**

Intestinal villi are highly vascular projections of the mucosal surface, just visible to the naked eye (Figs 66.15–66.17). They cover the entire intestinal mucosa, increase the surface area of the lumen about eight-fold, and give it a velvety texture. Villi are large
and numerous in the duodenum and jejunum, and smaller and fewer in the ileum. In the first part of the duodenum they appear as broad ridges, become tall and foliate in the distal duodenum and proximal jejunum, and then gradually shorten to a finger-like form in the distal jejunum and ileum. Villi vary in density from 10 to 40 per square millimetre and from 0.5–1.0 mm in height (Fig. 66.15). Infoldings of the mucosa dip down from the base of the villi for a short distance into the lamina propria. These crypts (of Lieberkühn), are most prominent in the proximal small intestine (Fig. 66.16).

![Fig. 66.15](image)

Fig. 66.15  Low power micrograph showing the wall of the duodenum, with villi (V) projecting into the lumen (L); intestinal crypts (IC) of Lieberkühn in the mucosa, seen mainly in transverse section; muscularis mucosae (arrows); submucosal seromucous (Brunner’s) glands (B) and muscularis externa (ME).

(By courtesy of Mr Peter Helliwell and Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)
Fig. 66.16 The architecture of an intestinal villus. The various layers and cells are not drawn to scale.
Mucosa

The mucosa consists of epithelium, lamina propria and muscularis mucosae.

Epithelium

A single-layered epithelium covers the intestinal villi (Figs 66.15, 66.16) and also lines the intestinal glands (crypts) that open between the bases of villi. Two types of cell, enterocytes and goblet cells, cover the surfaces of the villi, whereas microfold cells (M cells) are restricted to the dome epithelium that covers localized accumulations of lymphoid tissues. These cell types are all in contact basally with a basal lamina to which they adhere, and all are derived from a common stem cell in the intestinal crypts.

Enterocytes

Enterocytes are columnar absorptive cells, approximately 20 µm tall. They are the most numerous type of cell in the small intestinal lining, and are responsible for nutrient absorption. Their surfaces bear up to 3000 microvilli, which greatly increase the surface area for absorption. Collectively, microvilli are visible by light microscopy as a brush (striated) border 1 µm thick: individual microvilli can be resolved only by electron microscopy. Enterocyte nuclei are elongated vertically, mainly euchromatic and located just below the centre of the cell.

The apical cell surface is resistant to protease attack because microvilli possess a specialized glycoprotein-rich surface coat (glycocalyx) which, with an overlying layer of mucus, protects the epithelium against pancreatic enzymes in the intestinal lumen.
The cell coat also contains a number of digestive enzymes as integral membrane proteins. These include enzymes that degrade disaccharides and oligopeptides prior to absorption. Further details of the structure of microvilli are given on page 18).

The luminal surface is an important barrier to diffusion. Nutrients generally have to pass through enterocytes (transcellular absorption) before they reach the underlying lamina propria and its blood vessels and lymphatics (lacteals). Classical epithelial junctional complexes encircle the apical plasma membranes of adjacent enterocytes: their tight junctions form an effective barrier to non-selective diffusion between the gut lumen and the body as a whole. The lateral plasma membranes of enterocytes are highly folded, interdigitating with each other to form complex intercellular boundaries, anchored periodically by desmosomes, and making contact at gap junctions. The lateral intercellular space expands during active absorption and is an additional conduit (supplementing transport across the basal cell surface) for the passage of fluids, nutrients and other solutes to the vessels of the lamina propria.

Enterocytes have a lifespan after differentiation of about 5 days. Their position on the villus wall reflects their stage in the life cycle: at the tips of intestinal villi they undergo programmed, apoptotic, cell death and are shed from the epithelium. They are replaced at the base of the villus by stem cell mitosis.

Goblet cells

Goblet cells are most numerous in the distal small intestine, increasing in number from the duodenum to their highest density in the terminal ileum. They have elongated basal nuclei, an apical region containing many membrane-bound mucinogen granules, and apical surfaces that bear a few short microvilli. Goblet cell mucins contribute to protection against microorganisms and toxins in the gut lumen, and also provide lubrication and mechanical protection from the intestinal contents.

Microfold (M) cells

Microfold cells are present where the epithelium covers lymphoid aggregates in the intestinal wall (p. 74). They are cuboidal or flattened in shape and have long, widely spaced microfolds rather than microvilli on their apical surfaces. They sample luminal antigens by endocytosis, and transport antigen to lymphocytes lying within intercellular pockets formed by deep invaginations of the M-cell basolateral plasma membranes. See page 78 for details of antigen processing and presentation.

Lymphocytes

Intraepithelial lymphocytes are found in close association with M cells and also between the basolateral regions of enterocytes and goblet cells. They are migratory cells derived from the underlying lymphoid tissue and constitute an important means of immune defence.

Intestinal glands or crypts

Intestinal glands or crypts (of Lieberkühn) are tubular pits that open into the lumen throughout the intestinal mucosa via small circular apertures between the bases of the villi (Figs 66.14–66.16). Their thin walls are composed of columnar enterocytes supplemented by mucous cells, Paneth cells, stem cells and neuroendocrine cells.
They are separated by a basement membrane from a rich capillary plexus within the lamina propria.

Enterocytes

Enterocytes in the crypts secrete ions and alkaline fluid to dilute chyme and aid absorption by structurally similar cells that cover the villi.

Mucous cells

The mucous cells in the crypts are similar to the goblet cells of the villi.

Paneth cells

Paneth cells are numerous in the deeper parts of the intestinal crypts, particularly in the duodenum. They are rich in zinc and contain large acidophilic granules that stain strongly with eosin or phosphotungstic haematoxylin. Paneth cells secrete lysozyme, a highly specific antibacterial enzyme, and other defensive proteins (defensins) such as tumour necrosis factor alpha (TNF-\(\alpha\)), which protect the intestinal luminal surface.

Stem cells

Stem cells occur in a zone just above the basal region of the crypts and are the source of most of the cell types of the intestinal epithelium. Their progeny, transit (transient) amplifying cells, have one of the most rapid proliferation rates in the body. They migrate out of the intestinal crypts along the sides of the villi, where they differentiate mainly into the short-lived columnar enterocytes or goblet cells (which are thus continually replaced). When not dividing, their apical surfaces have fewer and more irregular microvilli than the differentiated enterocytes.

Neuroendocrine cells

Several types of neuroendocrine cell are scattered among the walls of the intestinal crypts, and less commonly over the villi. They secrete bioactive peptides, such as gastrin, cholecystokinin and secretin, basally into the surrounding lamina propria. Crypt neuroendocrine cells are derived from stem cells, which also give rise to enterocytes and other epithelial elements. For further details of the dispersed neuroendocrine system, see page Chapter 60.

Lamina propria

The lamina propria is composed of connective tissue and provides mechanical support for the epithelium. It has a rich vascular plexus, receives nutrients absorbed by the enterocytes, and forms the cores of the villi. It contains lymphoid tissue, fibroblasts and connective tissue extracellular matrix fibres, smooth muscle cells, eosinophils, macrophages, mast cells, capillaries, lymphatic vessels and unmyelinated nerve fibres. Plasma cells are numerous. Lymphocytes may be clustered in solitary or aggregated follicles, some of which extend through the muscularis mucosae into the submucosa.

Core of the villus

Each villus has a core of delicate connective tissue that contains a large blind-ending
lymphatic vessel or lacteal (so called because of its content of suspended chylomicrons, the droplets of apoprotein–lipid complex elaborated by enterocytes from absorbed dietary fats). The core also contains blood vessels, nerves and smooth muscle cells derived from fine extensions of the muscularis mucosae. Each lacteal, usually single but occasionally double, starts in a closed dilated extremity near the tip of a villus, and extends through the core to the base of the villus, where it joins a narrower lymphatic plexus in the deeper lamina propria. Its wall is a single layer of endothelial cells. Smooth muscle cells surround the lacteal throughout the villus and their contraction propels its contents into the underlying lymphatic plexus. Capillaries within the core are lined by fenestrated endothelium to facilitate the rapid intake of nutrients diffusing from the covering absorptive epithelium.

**Mucosa-associated lymphoid tissue**

Mucosa-associated lymphoid tissue (MALT) consists of lymphoid follicles covered by follicle-associated intestinal epithelium which includes scattered M cells. It is found mainly in the lamina propria, but sometimes expands into the submucosa, and is the source of B and T lymphocytes and other related cells involved in the immune defence of the gut wall.

Solitary lymphoid follicles are scattered along the length of the intestinal mucosa, and are most numerous in the distal ileum. Aggregated lymphoid follicles, Peyer's patches, are circular or oval masses containing 10–260 follicles. They vary in length from 2 to 10 cm, are visible macroscopically as dome-like elevations, and usually situated in the intestinal wall opposite the mesenteric attachment. They are largest and most numerous in the ileum; small, circular and few in the distal jejunum; and rare in the duodenum. Villi are small or absent over the larger follicular groups.

Like other masses of MALT (except lymph nodes), solitary and aggregated lymphoid follicles are most prominent around the age of puberty, after which they diminish in number and size, although many persist into old age. For further details of intestinal MALT and its function, including Peyer's patches, see Didierlaurent, Simonet & Sira (2006).

**Muscularis mucosae**

The muscularis mucosae forms the base of the mucosa, and has external longitudinal and internal circular layers of smooth muscle cells. It follows the surface profiles of the circular folds and sends fine fascicles of smooth muscle cells into the cores of the villi.

**Submucosa**

The submucosa is composed of loose connective tissue and contains blood vessels, lymphatics and nerves. Its ridged elevations form the cores of the circular folds. The geometry of its collagen and elastin fibres permits the considerable changes in transverse and longitudinal dimensions that accompany peristalsis, whilst still providing adequate support, elasticity and strength.

**Submucosal (Brunner's) glands**

Submucosal glands are limited to the submucosa of the duodenum and often referred to as ‘Brunner's glands’ (see Fig. 66.15). Their ducts traverse the muscularis mucosae
to enter the bases of the mucosal crypts. They are largest and most numerous near the pylorus and form an almost complete layer in the proximal half of the descending duodenum, thereafter they gradually diminish in number and disappear at the duodenojejunal junction. They are small, branched tubuloacinar glands: each has several secretory acini lined by low columnar epithelial cells that produce an alkaline (pH 9) mucoid secretion which effectively neutralizes acidic chyme from the stomach. Many neuroendocrine cells are present among the acinar cells.

**Muscularis externa**

The muscularis externa consists of a thin external longitudinal layer and a thick internal circular layer of smooth muscle cells. It is thicker in the proximal small intestine and is mainly responsible for the differential appearance of proximal jejunum and distal ileum of CT scanning.

**Serosa**

Serosa is visceral peritoneum and consists of a subserous stratum of loose connective tissue covered by mesothelium. It covers the majority of the muscularis externa, the only exceptions are the part adjacent to mesenteric adipose tissue and the retroperitoneal portions of the duodenum, both of which are covered mainly by a connective tissue adventitia rather than by serosa.

CHAPTER 67 – Large intestine

OVERVIEW

The large intestine extends from the ileocaecal valve to the anus. Broadly speaking, it lies in a curve which tends to form a border around the loops of small intestine that are located centrally within the abdomen (Figs 67.1, 67.2). The large intestine begins in the right iliac fossa as the caecum, from which the vermiform appendix arises. The caecum becomes the ascending colon which passes upwards in the right lumbar region and hypochondrium to the inferior aspect of the liver where it bends to the left forming the hepatic flexure (right colic flexure) and becomes the transverse colon. This loops across the abdomen with an anteroinferior convexity until it reaches the left hypochondrium, where it curves inferiorly to form the splenic flexure (left colic flexure) and becomes the descending colon, which proceeds through the left lumbar and iliac regions to become the sigmoid colon in the left iliac fossa. The sigmoid colon descends deep into the pelvis and becomes the rectum which ends in the anal canal at the level of the pelvic floor. The large intestine is approximately 1.5 m long in adults, although there is considerable variation in its length. Its calibre is greatest near the caecum and gradually diminishes to the level of the sigmoid colon. The rectum is largest in calibre in its lower third and forms the rectal ampulla above the anal canal.
Fig. 67.1 Overview of the abdominal colon and its relations.
The large intestine differs from the small intestine in several ways: it has a greater calibre; for most of its course it is more fixed in position; its longitudinal muscle, though a complete layer, is concentrated into three longitudinal bands, taeniae coli, in all but the distal sigmoid colon and rectum; small adipose projections, appendices epiploicae, are scattered over the free surface of the whole colon (they tend to be absent from the caecum, vermiform appendix and rectum); the colonic wall is puckered into sacculations (haustrations), which may partly be due to the presence of the taeniae coli, and which may be demonstrated on plain radiographs as incomplete septations arising from the bowel wall.

The large intestine develops as a fully mesenteric organ. However, after the rotation of the gut tube in utero, large portions of it come to lie adherent to the retroperitoneum, which means that some parts of the colon are fixed within the retroperitoneum, and other parts are suspended by a mesentery within the peritoneal cavity. Those portions of the colon within the retroperitoneum are separated from other retroperitoneal structures by a thin layer of connective tissue which forms an avascular field during surgical dissection, but which offers little or no barrier to the spread of disease within the retroperitoneum.

The caecum may be within the retroperitoneum, but more frequently is suspended by a short mesentery. The ascending colon is usually a retroperitoneal structure although the hepatic flexure may be suspended by a mesentery. The transverse colon emerges from the retroperitoneum on a rapidly elongating mesentery and lies, often freely mobile, in the upper abdomen. The transverse mesocolon shortens to the left of the upper abdomen and may become retroperitoneal at the splenic flexure. Occasionally the splenic flexure is suspended by a short mesentery. The descending colon is retroperitoneal usually to the level of the left iliac crest. As the colon enters the pelvis it becomes increasingly more mesenteric again at the origin of the sigmoid colon, although the overall length of the sigmoid mesentery is highly variable. The distal sigmoid colon lies on a rapidly shortening mesentery as it approaches the pelvis; by the level of the rectosigmoid junction the mesentery has all but disappeared, so that
the rectum enters the pelvis as a retroperitoneal structure. The caecum and proximal ascending colon are often more mobile on a longer mesentery in the neonate and infant than they are in the adult.

The mesenteries of the colon consist of visceral peritoneum enclosing connective and adipose tissues which envelop the vessels, nerves and lymphatics as they course from the retroperitoneum. Where the colonic mesenteries lie in contact with the retroperitoneum, the (potential) space between the retroperitoneum and mesentery is referred to as the subperitoneal space, which allows free tracking of pathological processes in either direction.

**EXTERNAL APPEARANCE**

The haustrations of the colon are often absent in the caecum proximal to the origin of the ascending colon and are often relatively sparse in the ascending and proximal transverse colon. In these regions the taeniae coli are usually thin and occupy only a small percentage of the circumference of the colon. There are few if any appendices epiploicae on the serosal surface of the caecum, and only a limited number on the surface of the ascending colon. The haustrations become more pronounced from the middle of the transverse colon to the distal portion of the descending colon: the sigmoid colon is often characterized by marked sacculation. The width of the taeniae coli remains fairly constant throughout the length of colon but the number of appendices epiploicae usually increases, becoming in the sigmoid colon where they can be large in the obese individual. The taeniae are located in fairly constant positions beneath the serosal surface of the colon except in the transverse colon. They are oriented anteriorly on the anti-mesenteric aspect of the colon opposite the midline of the mesenteric attachment (taenia libera), posterolaterally (taenia omentalis) and posteromedially (taenia mesocolica) midway between the taenia libera and the mesentery (Fig. 67.3). In the caecum and descending colon, which are partly retroperitoneal structures, the posterolateral taenia is often obscured from view by the peritoneal reflection onto the colonic wall. In the transverse colon, the taeniae are rotated through 90° as a consequence of the mobility and dependent position of this part of the colon, thus anterior becomes inferior, posteromedial becomes posterior and posterolateral becomes superior. The taeniae coli broaden to occupy more of the circumference of the sigmoid colon in its distal portion and by the level of the rectosigmoid junction they form distinct anterior and posterior bands. These bands subsequently unite to form a complete longitudinal muscle covering for the rectum which therefore has no external sacculation. The rectum also lacks serosal appendices epiploicae.
Fig. 67.3 Layers of the colonic wall.
INTERNAL APPEARANCE

Throughout its length, the internal aspect of the colon is characterized by the presence of haustrations. These infoldings of the wall consist of mucosa and submucosa, and may partially span the lumen, but they never form a complete, circumferential ring. The pattern of the haustrations and appearance of the colonic mucosa help the clinician appreciate the level reached during flexible endoscopic examinations of the colon. In the portion of the caecum where haustrations occur, the three longitudinal taeniae coli converge to form a characteristic ‘trefoil’ pattern on the caecal wall (Fig. 67.4). Elsewhere, the wall of the lower pole of the caecum is usually devoid of haustrations, although a spiral mucosal pattern is often seen in the region of the appendix orifice (see Fig. 67.19). The upper caecum and ascending colon possess shallow but long haustrations which may extend across one-third of the lumen (Fig. 67.5). This pattern is most pronounced in the transverse colon where the long haustrations often confer a triangular appearance to the cross section of the lumen when viewed along the axis (such as at colonoscopy) (Fig. 67.6). The wall of the colon is thinnest in the region of the caecum and ascending colon and is most at risk of perforation during therapeutic endoscopic procedures. The haustrations of the descending and sigmoid colon tend to be thicker and shorter than those of the transverse colon, and this gives a more circular cross-section to the lumen. The overall luminal diameter is often smallest in the descending colon (Fig. 67.7). During endoscopy, the pattern of the submucosal vessels becomes more conspicuous in the sigmoid colon (Fig. 67.8). The mobility of the sigmoid colon on its mesentery means that shorter lengths of colon tend to be visible during endoscopy than anywhere else in the colon. The haustrations of the rectum tend to form consistent and recognizable folds: the pattern of the submucosal vessels is the most pronounced in the colon being of largest calibre with multiple visible veins (Fig. 67.9). Distinct veins are usually visible during endoscopy, and they are most marked above the anorectal junction.
Fig. 67.4 Endoscopic appearance of the caecum. The characteristic trefoil appearance of the confluence of the three taeniae is usually obvious.
Fig. 67.19 Endoscopic appearance of the orifice of the appendix. The orifice varies from a small depression to an obvious lumenal structure.
Fig. 67.5 Endoscopic appearance of the ascending colon.

- Heocacal valve
Fig. 67.6  Endoscopic appearance of the transverse colon. Note the characteristic triangular appearance of the haustrations when viewed collectively (see also Fig. 67.10C).
Fig. 67.7 Endoscopic appearance of the descending colon. The lumen tends to look rather more featureless than the more proximal colon.
Fig. 67.8  Endoscopic appearance of the sigmoid colon. Multiple large mucosal folds are characteristic.
**Fig. 67.9** Endoscopic appearance of the rectum. Note the large transverse folds, with little else in the way of mucosal folds, characterizes the rectum. Prominent veins are often seen, particularly in the lower third.
RADIOGRAPHIC APPEARANCES

Cross-sectional imaging of the colon can be performed with computerized tomography (CT) and magnetic resonance imaging (MRI). On axial imaging the colon may be filled with particulate faeces and air (Fig. 67.10). The wall in normal individuals is thin. The caecum and ascending colon often contain faecal residue and are easily identified in the right retroperitoneum. The transverse colon may contain faeces or gas, but lies in a variable position suspended by its mesentery. The descending colon in the left retroperitoneum is frequently collapsed and contains little faecal residue.

Fig. 67.10 Appearance of the colon on multislice computerized tomographic examination. A, Axial CT. B, Coronal reformat showing normal calibre and distribution of the abdominal colon (ascending, transverse and descending). C, Volume-rendering of the colonic wall using the axial data set to produce virtual colonoscopic views, showing the triangular lumen of the transverse colon. D, Volume-rendering of the air-filled colon using the axial data set to give an image similar to a double contrast barium enema demonstrating hastrations. (A and B by courtesy of Dr Louise Moore, Chelsea and Westminster Hospital.) (C and D by courtesy of GE Worldwide Medical Systems.)

The volume data sets produced by modern multislice CT can now produce virtual colonoscopic mucosal images in the distended and cleaned colon, and surface-
rendered images of the internal surface of the bowel.
**VASCULAR SUPPLY AND LYMPHATIC DRAINAGE**

**Arteries**

The arterial supply of the large intestine is derived from both the superior and inferior mesenteric arteries (Fig. 67.11). The caecum, appendix, ascending colon and right two-thirds of the transverse colon (derived from the midgut) are supplied from ileocolic, right colic and middle colic branches of the superior mesenteric artery. The left part of the transverse, descending and sigmoid colon, rectum and upper anal canal (hindgut derivatives) are supplied predominantly from the inferior mesenteric artery via the left colic, sigmoid and superior rectal arteries, with small contributions from branches of the internal iliac artery (the middle and inferior rectal arteries). The larger unnamed branches of these vessels ramify between the muscular layers of the colon which they supply. They subdivide into smaller submucosal rami and enter the mucosa. The terminal branches divide into vasa brevia and vasa longa which either enter the colonic wall directly or run through the subserosa for a short distance before crossing the circular smooth muscle to give off branches to the appendices epiploicae (Fig. 67.12).
Fig. 67.11 The main branches of the superior and inferior mesenteric arteries.
The arterial supply to the large intestine has less profuse anastomoses and 'crossover' of arterial territories than the small intestine but there are several areas and anastomoses which provide for some degree of anatomical collateral supply to areas of the large intestine.

The marginal artery (of Drummond) of the colon is the name given to the vessel which lies closest to and parallels the wall of the large intestine. It is formed by the main trunks, and the arcades arising from, the ileocolic and right colic, middle colic and left colic arteries. It is most apparent in the ascending, transverse and descending colons (Fig. 67.13). The sigmoid colon has little if any marginal artery. Anastomoses form between the main terminal branches which run parallel to the colon within the mesentery and give rise to vasa recta and vasa brevia to supply the colon. The marginal artery in the region of the splenic flexure may be absent or of such small calibre as to be of little clinical relevance. It may hypertrophy significantly when one of the main visceral arteries is compromised, e.g. following stenosis or occlusion of the inferior mesenteric artery, and it then provides a vessel of collateral supply.
The marginal artery running parallel to the colon and anastomosing with the branches of the superior mesenteric artery supplying the right side of the colon, digital subtraction arteriogram. (By courtesy of Dr J Jackson, Hammersmith Hospital, London.)

The arc of Riolan is the name given to the arterial anastomosis which is sometimes present in the mesentery between the right side of the transverse colon and the upper descending colon. When present it is formed from a large branch of the middle colic artery which runs parallel and posterior to the middle colic artery in the transverse mesocolon and anastomoses with an ascending branch of the left colic artery close to its origin in the root of the mesentery. This provides a direct communication between the superior and inferior mesenteric arteries.

*Colonic vascular occlusion*
The marginal artery of the colon may become massively dilated when there is chronic, progressive occlusion of the superior mesenteric artery, because under these conditions it is required to supply the majority of the midgut (except the proximal portion which is supplied by collateral vessels from the coeliac artery). Occlusion of the aorta or common iliac arteries may also result in dilatation of the marginal and inferior mesenteric arteries, which become an important collateral supply to the legs via dilated middle rectal vessels arising from the internal iliac artery.

Oclusion of the inferior mesenteric artery does not always result in irreversible ischaemia of the descending and sigmoid colon, because the marginal artery of the colon usually receives an adequate supply from the left branch of the middle colic artery. Moreover, the sigmoid arteries may be supplied by the superior rectal artery, which anastomoses with the middle and inferior rectal arteries. When ischaemia does occur, it is usually maximal in the proximal descending colon because this region is furthest from the collateral arterial supplies.

Veins

The venous drainage of the large intestine is primarily into the hepatic portal vein via the superior mesenteric and inferior mesenteric veins, although a small amount of drainage from the rectum occurs via middle rectal veins into the internal iliac veins and via inferior rectal veins into the pudendal vein. Those parts of the colon derived from the midgut (caecum, appendix, ascending colon and right two-thirds of the transverse colon) drain into colic branches of the superior mesenteric vein, while hindgut derivatives (left part of the transverse, descending and sigmoid colon, rectum and upper anal canal) drain into the inferior mesenteric vein (Fig. 67.14).
Lymphatic vessels of the caecum, ascending and proximal transverse colon drain ultimately into lymph nodes related to the superior mesenteric artery, while those of the distal transverse colon, descending colon, sigmoid colon and rectum drain into nodes following the course of the inferior mesenteric artery (Fig. 67.15). In cases where the distal transverse colon or splenic flexure is predominantly supplied by vessels from the middle colic artery, the lymphatic drainage of this area may be predominantly to superior mesenteric nodes.
Colic nodes

Lymph nodes related to the colon form four groups, namely epicolic, paracolic, intermediate colic and preterminal colic nodes. Epicolic nodes are minute nodules on the serosal surface of the colon, sometimes in the appendices epiploicae. Paracolic nodes lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. Intermediate colic nodes lie along the named colic vessels (the ileocolic, right colic, middle colic, left colic, sigmoid and superior rectal arteries). Preterminal colic nodes lie along the main trunks of the superior and inferior mesenteric arteries and drain into para-aortic nodes at the origin of these vessels. These are commonly referred to as the highest nodes of the territory which they drain.

Lymph node clearance in colorectal cancer resections

Radical lymphadenectomy during resection for colorectal cancer requires removal of the highest possible lymph node draining the area of colon in which the tumour is located. In cases of cancer involving the rectum and sigmoid colon, this usually involves resection of the preterminal colic nodes of the inferior mesenteric artery and thus ligation of the inferior mesenteric artery at its root or just below the origin of the left colic artery. A detailed description of the classification of the lymph nodes with regard to the site of the primary tumour within the colon has been suggested by the Japanese Society for the Cancer of the Colon and Rectum.
INNERVATION

The colon and rectum are innervated by the sympathetic and parasympathetic systems (see Ch. 60; see Figs 60.2–60.4).

The sympathetic supply to the caecum, appendix, ascending colon and right two-thirds of the transverse colon originates in the fifth to the 12th thoracic spinal segments and are conveyed to the coeliac and superior mesenteric plexuses via the greater and lesser splanchnic nerves where they and synapse on ganglionic neurones. Postganglionic axons travel along branches of the superior mesenteric artery, and are distributed to the colon from periarterial plexuses. The parasympathetic supply is derived from the vagus nerve via the coeliac and superior mesenteric plexuses.

The sympathetic supply of the left third of the transverse colon, the descending and sigmoid colon, rectum and upper anal canal originates in the first and second lumbar spinal segments. The fibres are distributed via the lumbar splanchnic nerves through the abdominal aortic and the inferior mesenteric plexuses and via the sacral splanchnic nerves through the superior and inferior hypogastric plexuses. Postganglionic axons reach the gut wall via periarterial plexuses on branches of the inferior mesenteric artery. The parasympathetic supply travels via the pelvic splanchnic nerves (nervi erigentes) from cell bodies in the second to the fourth sacral spinal segments. Those distributed to the rectum and upper anal canal run via these plexuses; however, a large number of fibres pass directly through the retroperitoneal tissues to the splenic flexure, descending and sigmoid colon independently of the inferior mesenteric artery.

The ultimate distribution within the wall of the large intestine is similar to the small intestine. The colic sympathetic nerves are motor to the ileocaecal valve musculature and inhibitory to mural muscle in the colon and rectum. Some fibres are vasoconstrictor to the colic vasculature. Parasympathetic nerves are secretomotor to colorectal glands, motor to the colic and rectal musculature and inhibitory to the internal anal sphincter. Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves; pain impulses pass in visceral afferents travelling with the sympathetic and parasympathetic nerves supplying the rectum and the upper part of the anal canal.
CAECUM, VERMIFORM APPENDIX AND ASCENDING COLON

CAECUM

The caecum is a large blind pouch lying in the right iliac fossa below the ileocaecal valve, continuous proximally with the distal ileum and distally with the ascending colon. The blind-ending vermiform appendix usually arises on its medial side at the level of the ileal opening. Its average axial length is 6 cm and its breadth 7.5 cm. It rests posteriorly on the right iliacus and psoas major, with the lateral cutaneous nerve of the thigh interposed. Posteriorly lies the retrocaecal recess which frequently contains the vermiform appendix. The anterior abdominal wall is immediately anterior to the caecum except when it is empty, in which case the greater omentum and some loops of the small intestine may be interposed. Usually the caecum is entirely covered by peritoneum, but occasionally this is incomplete posterosuperiorly where it lies over the iliac fascia only separated from it by loose connective tissue.

In early fetal life the caecum is usually short, conical and broad based, with an apex turned superomedially towards the ileocaecal junction. As the fetus grows, the caecum increases initially in length more than in breadth, still with the apex turned superomedially; in the later stages of intrauterine growth, the proximal part of the caecum widens so that the caecum is still a conical shape, but the apex (from which the appendix arises) comes to point inferomedially. This infantile form persists throughout life in only a very small percentage of individuals. Occasionally the originally conical caecum becomes quadrate as a result of the outgrowth of a saccule on each side of the anterior taenia: the saccules are of equal size and the appendix arises from the depression between them instead of from the apex of a cone. In the normal adult form, the right saccule grows more rapidly than the left, forming a new ‘apex’. The original apex, with the appendix attached, is pushed towards the ileocaecal junction (Fig. 67.16).
The process of fluid and electrolyte reabsorption starts in the caecum but takes place largely in the ascending and transverse colon. The distensible nature and ‘sac-like’ morphology of the caecum permit storage of large volumes of semi-liquid chyme that enters from the small bowel via the ileocaecal valve. The large resting diameter of the caecum makes it most liable to distension during periods of increased intracolonic pressure and thus it is the most vulnerable portion of the large intestine to perforation secondary to dilatation (obstructed or otherwise).

Ileocaecal valve

The ileum opens into the posteromedial aspect of the large intestine at the junction of the caecum and colon via the ileocaecal ‘valve’. The orifice has two flaps which project into the lumen of the large intestine (Fig. 67.17). The precise shape and form of the valve varies; in the cadaveric caecum the flaps are often semilunar, but in life they can often be seen to form a rosette or trefoil pattern of mucosa. The upper flap, approximately horizontal, is attached to the junction of the ileum and colon; the lower flap is longer and more concave, and is attached to the junction of the ileum and caecum. At their ends the flaps fuse, continuing as narrow membranous ridges, the frenula of the valve. The orifice may appear in many different shapes depending on the state of contraction or distension of the caecum; it is commonly either a slit or an oval.
The margin of the ileocaecal valve is formed by a reduplication of the intestinal mucosa and circular muscle. Longitudinal muscle fibres are partly reduplicated as they enter the valve, but the more superficial fibres and the peritoneum continue from the small to the large intestine without interruption. The valve may prevent reflux of chyme from the caecum to the ileum, and may slow the passage of ileal contents into the caecum when the circular muscle of the valve is contracted by sympathetic stimulation. Although circular and longitudinal muscle layers of the terminal ileum continue into the valve, there is little evidence that it constitutes a true functional sphincter.

The ileal valvular surfaces are covered with villi and have the structure of the small
intestinal mucosa, whereas their caecal surfaces have no villi but display numerous orifices of tubular glands peculiar to the colonic mucosa.

**Caecal volvulus**

Because the caecum and ascending colon may possess a mesentery to a variable degree, it is possible for the caecum (and lower portion of the ascending colon) to rotate about their mesenteric attachment (mesentero-axial volvulus) such that the lower pole of the caecum comes to lie in the left or right upper quadrant of the abdomen. The fixed apex of this rotation is formed by the attachment of the caecal mesentery to the retroperitoneum. Volvulus occurs most commonly in those individuals where a large portion of the ascending colon lies on a mesentery and the common origin of the caecal and ascending colic mesentery is narrow. It is extremely unlikely in individuals where the caecum and ascending colon possess a short broadly attached mesentery. True isolated volvulus of the caecum is extremely rare.
VERMIFORM APPENDIX

The vermiform appendix is a narrow, vermiform (worm-like) tube which arises from the posteromedial caecal wall, approximately 2 cm below the end of the ileum. It may occupy one of several positions (Fig. 67.18). The commonest positions seen in clinical practice are retrocaecal or retrocolic (behind the caecum or lower ascending colon respectively), pelvic, or descending (when the appendix hangs dependently over the pelvic brim, in close relation to the right uterine tube and ovary in females). Other positions, including subcaecal (below the caecum), and pre- or post-ilial (anterior or posterior to the terminal ileum respectively), are occasionally seen, especially when there is a long appendicular mesentery which allows greater mobility.

Fig. 67.18 The major positions of the appendix encountered at surgery or postmortem.
The three taeniae coli on the ascending colon and caecum converge on the base of the appendix, and merge into its longitudinal muscle. The anterior caecal taenia is usually distinct and can be traced to the appendix, which affords a guide to its location intra-operatively. The appendix varies from 2–20 cm in length: it is often relatively longer in children and may atrophy and shorten after mid-adult life. It is connected by a short mesoappendix to the lower part of the ileal mesentery. This fold is usually triangular, extending almost to the appendicular tip along the whole viscus.

The lumen of the appendix is small and opens into the caecum by an orifice lying below and slightly posterior to the ileocaecal opening. The orifice is sometimes guarded by a straight mucosal fold forming an asymmetrical ‘valve’ which gives the appendix orifice the appearance of a ‘strung bow’ (Fig. 67.19). This fold tends to lie parallel to the medial wall of the caecum and ileocaecal valve and an imaginary ‘arrow’ placed in the bow usually points in the direction of the ileocaecal valve; this is a useful sign during colonoscopic examinations. The lumen may be widely patent in early childhood but is often partially or wholly obliterated in the later decades of life.

Microstructure

The layers of the wall of the appendix are essentially those of the rest of the large intestine (see below) but some features are notably different and are described here. The serosa forms a complete covering, except along the mesenteric attachment. The longitudinal muscular fibres form a complete layer of uniform thickness, except over a few small areas where both muscular layers are deficient, so that the serosa and submucosa are in contact. At the base of the appendix, the longitudinal muscle thickens to form rudimentary taeniae that are continuous with those of the caecum and colon.

The submucosa typically contains many large lymphoid aggregates that extend from the mucosa and obscure the muscularis mucosae layer, which consequently is discontinuous. These aggregates also cause the mucosa to bulge into the lumen of the appendix, so that it narrows irregularly (Fig. 67.20). The mucosa is covered by a columnar epithelium as it is elsewhere in the large intestine, and the epithelium that overlies the mucosal lymphoid tissue contains M cells. Glands (crypts) are similar to those of the colon but are fewer in number and so are less densely packed. They penetrate deep into the lymphoid tissue of the mucosal lamina propria. The submucosal lymphoid tissue frequently exhibits germinal centres within its follicles, indicative of B-cell activation, as occurs in secondary lymphoid tissue elsewhere. Lymphoid follicles are absent at birth but accumulate over the first 10 years of life to become a prominent feature of the appendix. In adults, the normal layered structure of the appendix is lost and the lymphoid follicles atrophy and are replaced by collagenous tissue, and in the elderly, the appendix may be filled with fibrous scar tissue.
**Acute appendicitis**

The genesis of acute appendicitis varies between individuals. It may follow obstruction of the lumen, when it is a consequence of increased intraluminal pressure and retention of (infected) contents which allows acute suppuration to occur. The size of the orifice of the appendix in some individuals may contribute to the risk that this will happen. Appendicoliths may be visible on plain radiographs in 7–15% of the normal population: in those patients with acute abdominal pain, their presence indicates a high risk of appendicitis being present. The increased size of the orifice and lumen at the extremes of life may be a reason why acute appendicitis is relatively uncommon in these age groups. Acute appendicitis may also present as a primary suppuration of the tissues of the appendix itself: the reduction in appendicular lymphoid tissue that occurs in later life may be another reason why the disease is infrequent in the elderly. Although the appendix is well supplied by arterial anastomoses at its base, the appendicular artery is an end artery from the midpoint upwards and its close proximity to the wall makes it susceptible to thrombosis during episodes of acute inflammation. This may render the distal appendix ischaemic and explains the frequency of
gangrenous perforation seen in the disease.

The appendix and overlying visceral peritoneum are innervated by sympathetic and parasympathetic nerves from the superior mesenteric plexus. Visceral afferent fibres carrying sensations of distension and pressure mediate the symptoms of ‘pain' felt during the initial stages of appendicular inflammation. In keeping with other structures derived from the midgut, these sensations are poorly localized initially, and referred to the central (periumbilical) region of the abdomen. It is not until parietal tissues adjacent to the appendix become involved in any inflammatory process that somatic nociceptors are stimulated, and there is an associated change in the nature and localization of pain. The caecum and proximal ascending colon share a common innervation with the appendix (sympathetic and parasympathetic nerves via the superior mesenteric plexus), which means that early inflammation in the caecum (typhlitis) results in similar visceral pain symptoms to those experienced in appendicitis.
**ASCENDING COLON**

The ascending colon is approximately 15 cm long and narrower than the caecum. It ascends to the inferior surface of the right lobe of the liver, on which it makes a shallow depression, and then turns abruptly forwards and to the left, at the hepatic flexure. It is a retroperitoneal structure covered anteriorly and on both sides by peritoneum. Its posterior surface is separated by loose connective tissue from the iliac fascia, the iliolumbar ligament, quadratus lumborum, the aponeurosis of transversus abdominis, and the anterior peri-renal fascia inferolateral to the right kidney. The lateral femoral cutaneous nerve, usually the fourth lumbar artery, and sometimes the ilioinguinal and iliohypogastric nerves, lie posteriorly as they cross quadratus lumborum. Laterally the peritoneum forms the lateral paracolic gutter and medially the medial paracolic gutter (Fig. 67.21). The ascending colon possesses a narrow mesocolon for part of its course in up to one-third of cases. Anteriorly it is in contact with loops of ileum, the greater omentum and the anterior abdominal wall.
Hepatic flexure

The hepatic flexure forms the junction of the ascending and transverse colon as the latter turns down, forwards and to the left. It is variable in position and usually has a less acute angle than the splenic flexure. The anterior surface of the lower pole of the right kidney is posterior, the right lobe of the liver is superior and anterolateral (Fig. 67.22), the descending (second) part of the
duodenum is medial and the fundus of the gallbladder is anteromedial. The posterior aspect of the hepatic flexure is not covered by peritoneum and the gut wall is in direct contact with pararenal fascia. The hepatic flexure is often covered in the greater omentum which may be attached to the anterior surface both of the upper ascending colon and the proximal (right) end of the transverse colon.

Fig. 67.22 Axial CT images of the ascending colon obtained (A) at the level of the mid ascending colon and (B) at the level of the hepatic flexure, showing the relationship of the ascending colon and hepatic flexure to the right lobe of the liver, the right and left kidneys, the second part of the duodenum, and the gallbladder (supplied by Dr Louise Moore, Chelsea and Westminster Hospital, London).
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Superior mesenteric artery

The arteries to the caecum, appendix and ascending colon are somewhat variable, but all are derived from the superior mesenteric artery via the ileocolic and right colic (when present) arteries (see Figs 67.11, 67.13).

Ileocolic artery

The ileocolic artery arises from the right side of the superior mesenteric artery in its upper half in the root of the mesentery. It descends to the right beneath the parietal peritoneum towards the caecum and crosses anterior to the right ureter, gonadal vessels and psoas major to enter the right iliac fossa. Although the terminal distribution varies, the artery usually divides into a superior division which runs superolaterally towards the ascending colon where it anastomoses with the right colic artery (or right branch of the middle colic artery), and an inferior division which anastomoses with the final ileal branch of the distal superior mesenteric artery. The inferior division approaches the superior border of the ileocolic junction. It usually gives rise to the following branches: ascending colic (which passes up on the ascending colon to anastomose with the superior division), anterior caecal, posterior caecal (which usually gives rise to the appendicular artery) and ileal (which ascends to the left on the lower ileum, supplies it and anastomoses with the last ileal branch of the superior mesenteric artery (Fig. 67.23). The caecum is supplied almost entirely from the ileocolic artery.
The ileocolic artery is the most prominent vessel in the lower right colic mesentery and traction on the caecum in the direction of the anterior superior iliac crest will readily cause the vessel to ‘tent’ the mesentery due to its direct course towards the caecum. This allows easy identification of the vessel during laparoscopic surgery.

The appendicular artery descends behind the terminal ileum to enter the mesoappendix a short distance from the appendicular base (Fig. 67.23). Here it gives off a recurrent branch, which anastomoses at the base of the appendix with a branch of the posterior caecal artery: the anastomosis is sometimes extensive. The main appendicular artery approaches the tip of the organ, at first near to, and then in the edge of, the mesoappendix. The terminal part of the artery lies on the wall of the appendix and may be thrombosed in appendicitis, which results in distal gangrene or necrosis. Accessory arteries are common, and many individuals possess two or more arteries of supply to the appendix.

The arcades of the terminal ileal artery provide a collateral supply to the caecum via anastomoses with the ileal branch of the ileocolic artery.

**Right colic artery**

The right colic artery is a small vessel that is highly variable in its anatomy (Fig. 67.24). Most commonly it arises as a common trunk with the middle colic artery. Alternatively it may arise as a separate branch from the right side of the superior mesenteric artery, or from the ileocolic artery (when it is referred to as an accessory right colic artery), and occasionally it may be absent. From its origin in common with
the middle colic artery it passes towards the ascending colon, deep to the parietal peritoneum and anterior to the right gonadal vessels, right ureter and psoas major. Sometimes it arises more superiorly and crosses the second part of the duodenum and inferior pole of the right kidney. Near the colon it divides into a descending branch, which anastomoses with the ileocolic artery, and an ascending branch which anastomoses with the right branch of the middle colic artery. These form the marginal artery in the area of the hepatic flexure from which vessels are distributed to the upper third of the ascending colon, and the right side of the transverse colon.

**Fig. 67.24** Anatomical variants of the right colic artery.

**Veins**

Venous blood from the wall of the caecum, appendix and ascending colon drains into mesenteric arcades and subsequently into segmental veins, which accompany their respective arteries and tend to follow variations in arterial drainage. The segmental veins drain into the superior mesenteric vein, which lies to the right of the mesenteric artery.

**Superior mesenteric vein**

The superior mesenteric vein receives one or more middle colic veins, the right colic vein and the ileocolic vein and drains into the portal vein (see Figs 67.31, 66.12).
The inferior mesenteric artery.

Ileocolic vein

The tributaries of the ileocolic vein follow a broadly similar pattern to the branches of the ileocolic artery, and are formed from superior and inferior tributaries. The vein ascends alongside the ileocolic artery beneath the peritoneum of the ileocaecal mesentery and drains into the superior mesenteric vein. The inferior tributary receives appendicular veins (via the posterior caecal or ileocolic veins) and anterior and posterior caecal and ileal veins, and the superior tributary drains the ascending colic veins.

Ascending tributaries of the ileocolic and right colic veins accompany their respective arteries into the root of the mesentery and drain via the ileocolic vein into the superior mesenteric vein.
Right colic vein

The right colic vein is highly variable and may drain into the superior mesenteric vein directly, or the right gastroepiploic or inferior pancreaticoduodenal vein to form a ‘gastrocolic trunk’ which drains into the superior mesenteric vein, or it may be absent entirely.

Lymphatics

Lymphatic vessels originate from both anterior and posterior aspects of the colon and drain into nodes located along the branches of the ileocolic and the right colic arteries. Lymphatic drainage from the distal ascending colon and hepatic flexure may be predominantly to the nodes of the right colic artery. The lymphatic anastomoses are rich and the preterminal nodes for both routes of drainage are the ileocolic nodes, located close to the superior mesenteric artery (Fig. 67.15).

Lymphatic vessels in the appendix are numerous and there is abundant lymphoid tissue in its walls. From the body and apex of the appendix, 8–15 vessels ascend in the mesoappendix, occasionally interrupted by one or more nodes. They unite to form three or four larger vessels which run into the lymphatic vessels that drain the ascending colon, and end in the inferior and superior nodes of the ileocolic chain.
INNERVATION

The sympathetic supply to the caecum, appendix and ascending colon originates in the intermediolateral grey matter of the fifth to the 12th thoracic spinal segments. Preganglionic axons travel via the greater and lesser splanchnic nerves to the coeliac and superior mesenteric plexuses where they synapse on neurones in the coeliac and superior mesenteric ganglia; postganglionic axons form periarterial plexuses along the branches of the superior mesenteric artery, whence they are distributed to the walls of the colon.

The parasympathetic supply to the caecum, appendix and ascending colon is derived from the vagus nerve via the coeliac and superior mesenteric plexuses.

Referred pain

The appendix and overlying visceral peritoneum are innervated by sympathetic and parasympathetic nerves from the superior mesenteric plexus. Visceral afferent fibres carrying sensations of distension and pressure mediate the symptoms of ‘pain’ felt during the initial stages of appendicular inflammation. In keeping with other structures derived from the midgut, these sensations are poorly localized initially, and referred to the central (periumbilical) region of the abdomen. It is not until parietal tissues adjacent to the appendix become involved in any inflammatory process that somatic nociceptors are stimulated, and there is an associated change in the nature and localization of pain. The caecum and proximal ascending colon share a common innervation to the appendix (sympathetic and parasympathetic nerves via the superior mesenteric plexus); early inflammation in the caecum (typhlitis) results in similar visceral pain symptoms to appendicitis.
TRANSVERSE COLON

The transverse colon is approximately 50 cm long, and extends from the hepatic flexure in the right lumbar region across into the left hypochondriac region, where it curves posteroinferiorly below the spleen as the splenic flexure. It is highly variable in length and position, as may be confirmed by radiological assessment, but it often describes an inverted arch, with its concavity directed posteriorly and superiorly. Near the splenic flexure an abrupt U-shaped curve may descend lower than the main arch. The posterior surface at the hepatic flexure is devoid of peritoneum and is attached by loose connective tissue to the front of the descending part of the duodenum and the head of the pancreas. The transverse colon from here to the splenic flexure is almost completely invested by peritoneum. It is suspended from the anterior border of the body of the pancreas by the transverse mesocolon which is attached from the inferior part of the right kidney, across the second part of the duodenum and pancreas, to the inferior pole of the left kidney. The transverse colon hangs down between the flexures to a variable extent, and sometimes reaches the pelvis. Above it are the liver and gallbladder, the greater curvature of the stomach and the body of the spleen. The transverse colon is usually attached to the greater curvature of the stomach by the gastrocolic ligament, which is in continuity with the greater omentum, lying anteriorly and extending inferiorly. Behind and below the transverse colon lie the descending part of the duodenum, the head of the pancreas, the upper end of the small bowel mesentery, the duodenojejunal flexure and loops of the jejunum and ileum.

The transverse mesocolon permits considerable mobility of the transverse colon: occasionally the colon may be interposed between the liver and the diaphragm (Chilaiditi syndrome), and may be mistaken for free intraperitoneal gas.

SPLENIC FLEXURE

The splenic flexure forms the junction of the transverse and descending colon and lies in the left hypochondrium, inferomedial to the lower pole of the spleen (Fig. 67.25). It is anterior to the pancreatic tail, and also to the left kidney, from which it is separated by the anterior perirenal fascia. The splenic flexure often adopts a very acute angle such that the end of the transverse colon overlaps the beginning of the descending colon; there may be peritoneal and omental adhesions between the two structures. It lies more superiorly and posteriorly than the right hepatic flexure; the visceral peritoneum covering its lateral aspect is often attached to the diaphragm at the level of the 10th and 11th ribs by the phrenicocolic ligament, which lies below the anterolateral pole of the spleen. Its position with respect to the spleen in variable: it usually lies directly inferomedial to the lower pole, forming the colic impression, but it may lie anterior to the splenic hilum, and
even a little above. In these cases, the visceral peritoneum is often adherent to the splenic capsule or hilar connective tissue; inadvertent, downwards traction on the splenic flexure during surgery may tear the capsule or hilar vessels. It may lie ‘low’ in the splenorenal recess with no direct attachment to the splenic capsule.

Fig. 67.25 Relations of the splenic flexure.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The proximal two-thirds of the transverse colon is supplied by the superior mesenteric artery via the middle colic artery (Fig. 67.11). The distal third is usually supplied by the ascending branch of the left colic artery via the marginal artery of the colon, although this is somewhat variable.

Middle colic artery

The middle colic artery usually arises from the anterolateral aspect of the superior mesenteric artery, either separately or as a common trunk with the right colic artery, just inferior to the uncinate process of the pancreas and anterior to the third part of the duodenum. Initially it passes inferiorly, then turns to run anteriorly and superiorly within the root of the transverse mesocolon, just to the right of the midline, and usually divides into a right and left branch. The right branch anastomoses with the right colic artery, and the left branch anastomoses with the left colic artery. The arterial arches thus formed lie 3 or 4 cm from the transverse colon, which they supply. Sometimes the middle colic artery divides into three or more branches within the transverse mesocolon, in which case the most lateral branches form the arterial anastomoses. An accessory or rarely a replaced middle colic artery may arise from the dorsal pancreatic, hepatic, inferior mesenteric or left colic arteries (Fig. 67.26). In the latter two instances the left half or more of the transverse colon will derive its arterial supply from the inferior mesenteric artery.

Veins

Superior mesenteric vein

The superior mesenteric vein receives one or more middle colic veins and the ileocolic vein (see Figs. 67.31, 66.12). The right colic vein is often absent or drains as a
tributary to the right branch of the middle colic vein.

**Middle colic veins**

Several tributaries drain into one or more middle colic veins which are highly variable in extent and position. The middle colic veins drain either into the superior mesenteric vein, just before its junction with the splenic vein, or directly into the hepatic portal vein.

**Lymphatics**

Lymph vessels drain into nodes along the middle colic arteries and then into the superior mesenteric nodes. The predominant lymphatic drainage of the splenic flexure is usually via nodes along the left colic artery which drain into the inferior mesenteric nodes: this arrangement is dependent on the arterial supply to the distal third of the transverse colon.
INNERVATION

The proximal two-thirds of the transverse colon is innervated by sympathetic and parasympathetic nerves via the superior mesenteric plexus. The distal third usually receives a sympathetic supply from the inferior mesenteric plexus and a parasympathetic supply that is derived partly from the inferior mesenteric plexus and partly from retroperitoneal fibres which travel in the pelvic splanchnic nerves that arise from neurones in the second, third and fourth sacral spinal segments. The sympathetic nerves are inhibitory to mural muscle in the transverse colon; some fibres are vasoconstrictor to the colic vasculature. Parasympathetic nerves are secretomotor to colic glands and motor to the colic musculature.
DESCENDING COLON

The descending colon is approximately 25 cm long. It descends through the left hypochondrium and lumbar region, initially following the lateral border of the lower pole of the left kidney, and then descending in the angle between psoas major and quadratus lumborum to the iliac crest. It then curves inferomedially, lying anterior to iliacus and psoas major, to become the sigmoid colon below the level of the iliac crest (inlet of the lesser pelvis). It lies on the retroperitoneum covered anteriorly and on both sides by peritoneum. Its posterior surface is separated by loose connective tissue from the anterior peri-renal fascia inferolateral to the left kidney, the aponeurosis of transversus abdominis, quadratus lumborum, iliacus and the most superolateral part of psoas major. The subcostal vessels and nerves, iliohypogastric, ilio-inguinal, lateral femoral cutaneous, femoral and genitofemoral nerves, and the fourth lumbar artery (usually), all lie posterior to the descending colon (Fig. 67.27). Loops of jejunum lie anteriorly. If the anterior abdominal walls are relaxed, the most inferior part of the descending colon may be directly palpated transabdominally. The descending colon is smaller in calibre, more deeply placed, and more frequently covered posteriorly by peritoneum, than the ascending colon.
Fig. 67.27 Posterior relations of the descending colon.
SIGMOID COLON

The sigmoid colon begins below the pelvic inlet and ends at the rectum. Characteristically it forms a mobile loop which normally lies in the lesser pelvis, but its length and form are the most variable of all colonic segments. It is usually completely invested in peritoneum and is attached to the lower posterior abdominal wall and the posterior wall of the false pelvis by the fan-shaped sigmoid mesocolon. The root of the sigmoid mesocolon has an inverted 'V' attachment to the posterior abdominal wall.

The sigmoid colon initially descends over the iliac crest into the false pelvis but thereafter its position is extremely variable. It may remain folded and principally in contact with, or adherent to, the peritoneum overlying iliacus, or it may cross the pelvic cavity between the rectum and bladder in males, or the rectum and uterus in females, and it may even reach the right pelvic wall. If long, the sigmoid loop may rise out of the pelvis into the abdominal cavity and lie in contact with loops of ileum. The sigmoid loop ends in a relatively constant position lying just to the left of the midline at the level of the third sacral body, where it bends inferiorly and is continuous with the rectum. The sigmoid loop is fixed at its junctions with the descending colon and rectum but quite mobile between them. Its relations are therefore variable (Fig. 67.28). Laterally are the left external iliac vessels, the obturator nerve, ovary or vas deferens and the lateral pelvic wall; posteriorly lie the left external and internal iliac and gonadal vessels, ureter, piriformis and sacral plexus; anteroinferiorly lie the bladder in males, or uterus and bladder in females; superiorly and to the right the sigmoid colon is in contact with loops of the ileum. The gonadal vessels and ureter lie in a distinct fascial plane which is the inferior extension of the anterior and posterior peri-renal fascia in the lower retroperitoneum and which is separate from the thin fascial coverings of the mesosigmoid. The plane between the two layers can be recognized during surgical dissection of the mesentery of the sigmoid colon because it does not contain the numerous small vessels which are often present in the loose connective tissue surrounding the ureter and gonadal vessels.
The position and shape of the sigmoid colon vary according to the length of the colon; the length and mobility of its mesocolon; the degree of distension (when distended the sigmoid colon rises into the abdominal cavity, and it sinks again into the lesser pelvis when empty); the condition of the rectum, bladder and uterus (the sigmoid colon tends to rise when these are distended, and to fall when they are empty). The length and diameter of the sigmoid colon vary in different races.

**SIGMOID VOLVULUS**

Rotation or volvulus may occur around the mesenteric attachment of the sigmoid colon, similar to the rotation of the caecum around its mesentery. Only the sigmoid colon is affected, because the descending colon rarely possesses sufficient mesentery to become involved in the rotation. Rotation usually involves at least 270°. Volvulus is more common when the length of the sigmoid colon increases, since this is associated with a 'fan-like' mesentery with a short retroperitoneal attachment. Volvulus does not occur in individuals where the sigmoid colon is short or where the mesentery is short and its attachment runs over the brim of the pelvis. The combination of anatomical features predisposing to sigmoid volvulus is most commonly found in sub-Saharan Africans and chronically institutionalized patients.
DIVERTICULAR DISEASE

The development of acquired diverticula occurs commonly in the sigmoid colon, particularly in white Caucasian populations. Their location appears to be related to the underlying anatomy of the wall of the colon. Thus, diverticula commonly occur midway between the anti-mesenteric and lateral taeniae, i.e. where the colonic wall is potentially weak, not only because the circular muscle lacks the support of the longitudinal muscle, but also because it is traversed here by arteries as they access the submucosal vascular plexus. The predilection of the diverticula for the sigmoid colon probably relates to causative factors rather than intrinsic differences in the structure of its walls. In marked contrast, congenital diverticula may occur anywhere throughout the colon, and are often found adjacent to the mesenteric attachment of the colon.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply of the descending colon is from the inferior mesenteric artery via its left colic branch, which also anastomoses with the marginal artery of the colon (in the region of the splenic flexure), and the sigmoid arteries (in the region of the junction with the sigmoid colon) (Figs 67.29–67.31).

Fig. 67.29 Digital subtraction arteriogram showing the inferior mesenteric artery and its branches. (By kind permission from Dr Adam Mitchell, Charing Cross Hospital, London.)
Inferior mesenteric artery

The inferior mesenteric artery is usually smaller in calibre than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the aorta at about the level of the third lumbar vertebra, 3 or 4 cm above the aortic bifurcation and below the third part of the duodenum. It descends in the root of the left colic mesentery initially anterior and then to the left of the aorta, crosses the origin of the left common iliac artery medial to the left ureter, and then enters, and continues in, the root of the sigmoid mesocolon as the superior rectal artery. The inferior mesenteric vein lies on its lateral side in its distal course. The principal branches of the inferior mesenteric artery are the left colic, sigmoid and superior rectal arteries (see Figs 67.11, 67.29).

Left colic artery

The left colic artery arises from the inferior mesenteric artery shortly after its origin, ascends within the left colic mesentery anterior to the left psoas major, and bifurcates...
into ascending and descending branches (this division may occur soon after its origin). The artery or its branches cross the left ureter and gonadal vessels. The ascending branch passes anterior to the left kidney and anastomoses with the left branch of the middle colic artery in the subperitoneal space within the transverse mesocolon. The descending branch passes laterally in the retroperitoneum and approaches the descending colon, where it forms part of the marginal artery and anastomoses with the highest sigmoid artery. The arterial arches thus formed supply the distal third of the transverse and the descending colon. Occasionally an accessory, or rarely a replaced, left colic artery may originate from the trunk of the superior mesenteric artery or the first jejunal branches. When present, it runs laterally in the upper left colic mesentery just below the level of the duodenojejunal junction to supply the upper descending colon and form part or all of the marginal artery and the arterial anastomosis in the region of the distal transverse colon (Fig. 67.32). The left colic artery may itself give rise to an accessory left middle colic artery. Occasionally the left colic artery gives rise to a branch shortly after its origin which ascends in the mesentery and anastomoses directly with a similar descending branch of the left branch of the middle colic artery (the arc of Riolan).
Fig. 67.32 Replaced left colic artery arising from the superior mesenteric artery.

**Sigmoid (inferior left colic) arteries**

There are between two and five sigmoid arteries, which are branches of the inferior mesenteric artery. They descend obliquely within the subperitoneal space in the sigmoid mesentery, anterior to the left psoas major, ureter and gonadal vessels. They supply the distal descending colon and sigmoid colon, and anastomose superiorly with the left colic artery and inferiorly with the superior rectal artery. Unlike the small intestine, arterial arcades do not form until the arteries are close to the wall of the colon, when small branches arise which supply the sigmoid colon directly. The formation of a true marginal artery is less pronounced in the region of the sigmoid colon than in the region of the descending colon. A significant space often exists in the mesentery between the highest sigmoid artery and the descending branch of the
left colic artery: this is a useful guide to the arterial territories during surgical dissection.

In the region of the splenic flexure the marginal artery receives contributions from the left branch of the middle colic artery which anastomoses with an ascending branch of the left colic artery to supply the upper descending colon. The descending branch of the left colic artery anastomoses with upper branches of the highest sigmoid artery to supply the descending colon. The origin of the primary arterial supply for the splenic flexure and distal third of the transverse colon is usually via the left colic artery but may be from the left branch of the middle colic artery. The marginal artery in the region of the splenic flexure may be absent or of such small calibre as to be of little clinical relevance. It may, however, hypertrophy significantly when one of the main visceral arteries is compromised, e.g. following stenosis or occlusion of the inferior mesenteric artery, and it then provides a vessel of collateral supply.

**Vascular ligation in left colonic resections**

During resection of the distal descending and sigmoid colon, ligation of the inferior mesenteric artery close to its origin preserves the bifurcation of the left colic artery. The arterial supply to the proximal descending colon is maintained via the anastomosis between the ascending branch of the left colic artery and the left branch of the middle colic artery. Less radical resection, involving ligation of the left colic artery close to its bifurcation, may interfere with or obliterate this supply and render the descending colon more likely to become ischaemic. The same is true for ligation of the left colic vein. If the inferior mesenteric vein is ligated, then the bifurcation of the vein forms the route of venous drainage for the descending colon to the middle colic vein territory. Ligation of the branches separately will impair the venous drainage.

**Veins**

**Inferior mesenteric vein**

The inferior mesenteric vein drains the rectum, sigmoid, descending and distal transverse colon (Fig. 67.33; see also Fig. 67.14). It begins as the superior rectal vein, from the rectal plexus, through which it connects with middle and inferior rectal veins. The inferior mesenteric vein lies to left of the inferior mesenteric artery, ascends deep to the peritoneum and anterior to the left psoas major and may cross the testicular or ovarian vessels or ascend medial to them. It usually lies lateral to or occasionally posterior to the duodenojejunal flexure and the peritoneal fold directly lateral to the flexure is a useful guide to locating the vein surgically. It usually drains into the splenic vein, but occasionally drains into the confluence of the splenic and superior mesenteric veins or directly into the superior mesenteric vein. If a duodenal or paraduodenal fossa exists, the vein is usually in its anterior wall. The inferior mesenteric vein receives tributaries from several sigmoid veins, the middle and the left colic veins.
Left colic vein

The left colic vein is formed from several tributaries including ascending and descending branches which correspond to the equivalent arteries. These tributaries may not form a discrete vein until they drain into the inferior mesenteric vein, and occasionally there may be two distinct veins which both run into the inferior mesenteric vein. The left colic vein usually lies more superiorly in the left colon mesentery than its equivalent artery, and has a shorter course because the inferior mesenteric vein lies more laterally than the inferior mesenteric artery.

Several sigmoid veins drain the sigmoid colon and run superiorly alongside their
respective arteries to drain into the inferior mesenteric vein.

**Lymphatics**

Lymph vessels drain from the descending colon into nodes along the left colic artery, and from the sigmoid colon into sigmoid nodes in the sigmoid mesocolon which then join superior rectal and left colic vessels. All of these nodes drain into the inferior mesenteric nodes.
INNERVATION

The sympathetic supply to the left third of the transverse colon and the descending and sigmoid colon originates in the first and second lumbar spinal segments, and runs in the upper lumbar splanchnic nerves: preganglionic axons synapse on neurones in the abdominal aortic and the inferior mesenteric plexuses, whence postganglionic axons reach the gut wall via periarterial plexuses on branches of the inferior mesenteric artery. These axons are inhibitory to the mural muscle of the colon and some fibres are vasoconstrictor to the colic vasculature.

The parasympathetic supply is via the pelvic splanchnic nerves. Some fibres run through the inferior and superior hypogastric plexuses and along branches of the inferior mesenteric artery, but many more pass directly through the retroperitoneal tissues, independent of the inferior mesenteric artery, to reach the splenic flexure and descending and sigmoid colon. Parasympathetic nerves are secretomotor to colic glands and motor to the colic musculature. Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves.
RECTUM

The rectum is continuous with the sigmoid colon at the level of the third sacral vertebra and terminates at the upper end of the anal canal. It descends along the sacrococcygeal concavity as the sacral flexure of the rectum, initially inferoposteriorly and then inferoanteriorly, to join the anal canal by passing through the pelvic diaphragm. The anorectal junction is 2–3 cm in front of and slightly below the tip of the coccyx, which is opposite the apex of the prostate in males. From this level the anal canal passes inferiorly and posteriorly from the lower end of the rectum. The posterior bend is termed the perineal flexure of the rectum and the angle it forms with the upper anal canal is the anorectal angle. The rectum also deviates in three lateral curves: upper, convex to the right; middle (the most prominent), convex to the left; lower, convex to the right. Both ends of the rectum are in the median plane (Fig. 67.34).

Although variable in absolute length, a common landmark used in clinical practice to define the rectum is a length of 15 cm above the external anal margin. The initial diameter is similar to that of the sigmoid colon, but more inferiorly it becomes dilated as the rectal ampulla. The rectum differs from the sigmoid colon in having no sacculations or appendices epiploicae. The taeniae blend approximately 5 cm above the rectosigmoid junction, forming two wide muscular bands which descend anteriorly and posteriorly in the rectal wall. These then fuse to form an encircling layer of longitudinal muscle, which invests the entire length of the rectum. At the rectal ampulla a few strands of the anterior longitudinal fibres pass forwards to the perineal body as the musculus recto-urethralis. In addition, two fasciculi of smooth muscle may pass anteroinferiorly from the anterior surfaces of the bodies of the second and third coccygeal vertebrae to blend with the longitudinal muscle fibres on the posterior wall of the anal canal, forming the rectococcygeal muscles.

The upper third of the rectum is covered by peritoneum on its anterior and lateral aspects. It is related anteriorly to the sigmoid colon or loops of ileum if these lie in the pelvis, otherwise it is related to the urinary bladder in males, or the cervix and body of the uterus in females. The middle third of the rectum is covered by peritoneum only on its anterior aspect. The peritoneum is reflected superiorly onto the urinary bladder in
males to form the rectovesical pouch, or onto the posterior vaginal wall in females to form the recto-uterine pouch (pouch of Douglas). The level of this reflection is higher in males; the rectovesical pouch is approximately 7.5 cm (about the length of the index finger) from the anorectal junction. In females the recto-uterine pouch is approximately 5.5 cm from the anorectal junction. In the male neonate, peritoneum extends on to the front of the rectum as far as the lower limit of the prostate. Superiorly the peritoneum is firmly attached to the muscle layer of the sigmoid colon by fibrous connective tissue, but as it descends onto the rectum it is more loosely attached by fatty connective tissue, which allows for considerable expansion of the upper half of the rectum (Figs 67.35, 67.36).

Fig. 67.35 A, Sagittal T2-weighted MRI of the rectum in a male. B, Line diagram illustrating main features in A.
There are no haustra in the rectum. When empty the mucosa forms a number of longitudinal folds in its lower part which become effaced during distension. The rectum commonly has three permanent semi-lunar transverse or horizontal folds, although the number can vary, which are most marked in rectal distension (Fig. 67.9). Two forms of horizontal fold have been recognized. One consists of the mucosa, a circular muscle layer and part of the longitudinal muscle, and is marked externally by an indentation. The other is devoid of longitudinal muscle and has no external marking. The most superior fold at the beginning of the rectum may be either on the left or right and occasionally encircles the rectal lumen. The middle fold is largest and most constant. It lies immediately above the rectal ampulla, projecting from the anterior and right wall just below the level of the anterior peritoneal reflection; the circular muscle is more marked in this fold than in the others. The most inferior and variable fold is found on the left below the middle fold. Sometimes a fourth fold is found on the left a little above the middle fold.

**MESORECTUM, RECTAL FASCIAE AND ‘SPACES’**

The mesorectum (mesentery of the rectum) and its contents are intimately related to the rectum down to the level of levator ani (Figs 67.37–67.39). It is a distinct compartment derived from the embryological hindgut. It contains the superior rectal artery and its branches, the superior rectal vein and its tributaries, the lymphatic vessels and nodes that lie along the superior rectal artery, branches from the inferior mesenteric plexus which descend to innervate the rectum, and loose adipose connective tissue.
The mesorectum is enclosed by mesorectal fascia, a distinct covering derived from the visceral peritoneum that is also called the visceral fascia of the mesorectum, fascia propria of the rectum or the presacral wing of the hypogastric sheath. The fascia bounds the mesorectum posteriorly and thus lies anterior to the retrorectal space and the pre-sacral fascia. The mesorectal fascia is surrounded by a very thin layer of loose areolar tissue which separates it from the posterior and lateral walls of the true pelvis. Superiorly, the mesorectal fascia blends with the connective tissue bounding the sigmoid mesentery. Laterally, it extends around the rectum and mesorectum and becomes continuous with a denser condensation of fascia anteriorly.
In males this anterior fascia is known as the rectovesical fascia of Denonvillier, and in females it forms the fascia of the rectovaginal septum.

On MRI scanning, the mesorectum appears as a fat-containing envelope in which vessels are depicted as low signal due to signal void produced by blood flow. Lymph nodes appear as high signal ovoid structures. Small nerves within the mesorectum are not visualized, but interlacing connective tissue within the mesorectum can be seen as low signal intensity strands. The mesorectal fascia is demonstrated on axial views as a low signal layer that surrounds the mesorectum, and which corresponds to the distinct condensation of fascia seen on histological sections containing the mesorectum (Brown et al 1999). Identification of the involvement of this layer by malignant tumours of the rectum on MRI scanning may help plan preoperative radiotherapy, and predict the chance of successful surgical resection.

Anterolaterally, branches of the inferior hypogastric plexus and branches of the middle rectal artery and veins run into the mesorectum. They are ensheathed by fascia and are sometimes jointly referred to as the ‘lateral rectal ligaments’. The number and calibre of the middle rectal vessels are highly variable; they may be very small or even absent (Sato & Sato 1991). The ‘lateral ligaments’ are not seen on MRI or CT scanning, and only appear as an identifiable structure with surgical traction on the rectum. The fascia of the ‘ligaments’ is flimsy and they probably play very little role in support of the rectum.

The parietal fascia that covers levator ani and the muscles of the side-wall of the pelvis forms a denser condensation of fascial tissue overlying the sacrum (Fig. 67.40).

---

**Fig. 67.40** A, Light microscope transverse section of the mid rectum (male, cadaveric specimen). B, Line diagram illustrating main features in A.
RELATIONS OF THE RECTUM

Posterior to the rectum and mesorectum, and separated from them by the presacral fascia, in the median plane are the lower three sacral vertebrae, coccyx, median sacral vessels, and the lowest portion of the sacral sympathetic chain. Laterally, the upper part of the rectum is related to the pararectal fossa and its contents (sigmoid colon or terminal ileum), while below the peritoneal reflection lie piriformis, the anterior rami of the lower three sacral and coccygeal nerves, the sympathetic trunk, lower lateral sacral vessels, and coccygei and levatores ani. Anteriorly, above the level of the peritoneal reflection, lie loops of sigmoid colon or terminal ileum (if these lie in the pelvis), otherwise the rectum is related to the upper parts of the base of the bladder in males, or to the cervix/body of the uterus and upper vagina in females. The lower parts of the base of the bladder, the seminal vesicles, vas deferens, terminal parts of the ureters, and the prostate in males (Figs 67.38, 67.39), or the lower part of the vagina in females, lie below the reflection. In females, the rectovaginal septum is composed of a condensation of connective tissue which is continuous with the connective tissue of the outer layers of the rectal and vaginal walls. In postmenopausal females, and following childbirth, the connective tissue of the rectovaginal septum may atrophy or be thinned, reducing the support for the anterior rectal and posterior vaginal walls.
RECTAL PROLAPSE

Prolapse of the rectum involving all layers of the rectal wall may occur: the precise aetiology is not known. During prolapse, the mid and upper rectum descends towards the pelvic floor on straining. This descent tends to occur within the lumen of the rectum as a form of intussusception, and may be a consequence of the large diameter of the lower rectal ampulla and relative fixation of the anorectal junction and anal canal. The upper mesorectum is formed by relatively loose adipose connective tissue, and so relatively little tissue actually fixes the mid and upper rectum in position within the pelvis. The 'lateral ligaments' are composed mainly of vascular structures and offer only limited support against rectal descent. Chronic enlargement of the anorectal space bound by levatores ani commonly occurs in patients suffering rectal prolapse, but it is thought to be a consequence rather than a cause of the prolapse. During prolapse, the recto-uterine pouch in females also descends with the anterior rectal wall, and in extreme cases may become everted through the anus between the layers of rectal wall. This rarely happens to the rectovesical pouch in males.
RECTOCELE

When the rectovaginal septum is grossly effaced, especially in postmenopausal females, the pressure of defecation transmitted forward along the sacral flexure of the rectum can eventually cause bulging of the rectal wall into the posterior vagina, and, in extreme cases, through the vaginal introitus. Failure of support of the rectum and perineum by the puborectalis and pubovaginalis muscles contributes to this prolapse by allowing descent of the posterior perineum during straining.
MESORECTAL EXCISION IN RECTAL CANCER

An important concept in the oncological treatment of adenocarcinoma of the rectum is the integrity of the rectum and its mesorectal tissue. The epirectal and pararectal lymphatic tissues are located throughout the mesorectum. If the mesorectum is divided or disrupted during surgical excision of rectal carcinoma, involved nodes may be left *in situ*, which may predispose to local recurrence of tumour (Heald et al 1982). Oncological excision of the rectum involves mobilization of the rectum in the plane formed by the mesorectal fascia posterolaterally around the mesorectum. This plane allows the rectum and mesorectum to be removed as a whole without disruption of the presacral fascia and its underlying venous plexus. It is continuous with the plane between the mesentery surrounding the origin of the superior rectal artery and the presacral fascia over the sacral promontory, which is opened during mobilization of the origin of the inferior mesenteric artery prior to ligation. The mesorectal plane extends laterally and anteriorly, disrupted only by small branches of the middle rectal vessels, and is continuous with the rectovesical or rectovaginal fascia, which provides a similar oncological plane of dissection. Since the inferior hypogastric nerves are closely related to the plane of the mesorectal fascia in its upper third, dissection must spare the nerves if a degree of pelvic autonomic disturbance (bladder dysfunction and erectile dysfunction in males) is to be avoided following surgery. Complete excision of the rectum – total mesorectal excision – involves mobilization of this plane to the level of levatores ani. During the excision it is important to follow the sacral curve of the rectum to prevent entry into the presacral fascia or anoococcygeal ligament with subsequent bleeding from presacral vessels.
ABDOMINOPERINEAL EXCISION IN RECTAL CANCER

The posterior mesorectum is thinnest at its lowest extremity, where the mesorectal fascia becomes continuous with the periserosal tissues which condense on the outer muscle layer as it passes inside the fibres of puborectalis and it lies directly on the fascia of levator ani (endopelvic fascia) (see Fig. 63.4). Tumours penetrating through the rectal wall at this point may therefore lie in extremely close proximity to the mesorectal margin. Conventional dissection in the mesorectal plane as far as the pelvic floor may open this fascial space close to the tumour and abdominoperineal excision of the rectum should be conducted through the ischio-anal fossa, vertically through levator ani outside the puborectalis sling and into the mesorectal plane well above the area of contact with the pelvic floor to avoid opening this potential tumour plane.
LOCAL EXCISION OF THE RECTUM

Full thickness excision of lesions of the rectal wall is possible in those parts of the rectum lying in the extraperitoneal compartment, i.e. below the peritoneal reflections. The mesorectal adipose tissue contains any leakage of contents and provides support to the closure of the defect in the rectal wall. Since only the lower third of the rectum is wholly extraperitoneal, full thickness local excisions of the rectum should be avoided on the anterior wall of the middle third and anterolateral walls of the upper third of the rectum. The height to which such excision can be performed anteriorly in females is lower than in males, because the lower level of the peritoneal reflection makes entry into the peritoneal cavity more likely.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The principal arterial supply to the upper two-thirds of the rectum is the superior rectal artery. Branches of the middle rectal artery provide some additional supply to the middle third, and ascending branches of the inferior rectal artery supply the distal third. The median sacral artery (the terminal midline branch of the aorta), contributes a small branch which enters the posterior wall of the anorectal junction on the sacrorectal fascia (Fig. 67.41).

Superior rectal artery

The superior rectal artery is the principal continuation of the inferior mesenteric artery (Fig. 67.31). It descends into the pelvis in the sigmoid mesocolon, crosses the left common iliac vessels and passes over the sacral promontory usually just to the left of the midline. It is straddled by the inferior hypogastric nerves on either side. It lies anterior to the upper sacral vertebrae and passes into the upper mesorectum, then
descends, initially in the midline, and divides into two branches at the level of the third sacral vertebra. These lie initially posterolateral, then lateral, to the rectal wall as they descend one on each side of the rectum. Terminal branches pierce the muscle wall from the level of the upper mesorectum to enter the rectal submucosa, where they anastomose with ascending branches of the inferior rectal arteries.

**Middle rectal arteries**

The middle rectal arteries arise either directly from the anterior division of the internal iliac artery or from the inferior vesical artery (vaginal artery in females). They enter the mesorectum anterolaterally in the 'lateral rectal ligaments', and are frequently either absent or may be very small in calibre (Sato & Sato 1991). When present, they provide an arterial supply to the muscle of the mid and lower rectum, but form only poor anastomoses with the superior and inferior rectal arteries.

**Inferior rectal arteries**

The inferior rectal arteries are terminal branches of the internal pudendal arteries. They cross the ischio-anal fossa to enter the upper anal canal laterally where they branch. They supply the internal and external anal sphincters, the anal canal and the perianal skin. Ascending branches pass superiorly in the submucosal plain, and anastomose with the terminal branches of the superior rectal artery.

**Veins**

**Rectal venous plexus**

The rectal venous plexus surrounds the rectum, and connects anteriorly with the vesical plexus in males or the uterovaginal plexus in females. It consists of an internal part, beneath the rectal and anal epithelium, and an external part outside the muscular wall. In the anal canal the internal plexus displays longitudinal dilatations, connected by transverse branches in circles immediately above the anal valves. The dilatations are most prominent in the left lateral, right anterolateral and right posterolateral sectors. The internal plexus drains mainly to the superior rectal vein but connects widely with the external plexus. The inferior portion of the external plexus is drained by the inferior rectal vein into the internal pudendal vein, the middle portion by one or more middle rectal veins into the internal iliac vein, and its superior part by the superior rectal vein, which drains into the inferior mesenteric vein. Communication between portal and systemic venous systems is thus established in the rectal plexus.

**Superior rectal veins**

The superior rectal veins are formed from the internal rectal plexus. The tributaries of the superior rectal vein ascend in the rectal submucosa as about six vessels of considerable size which pierce the rectal wall approximately 7.5 cm above the anus. The branches unite to form the superior rectal vein, which runs along the superior rectal artery in the root of the mesorectum and mesosigmoid, crosses the left common iliac vessels with the superior rectal artery, and continues upwards as the inferior mesenteric vein to the left of the midline (see Figs 67.14 and 67.43A).
**Fig. 67.43** A. Coronal section through the anal canal: glandular and vascular structures are shown unilaterally for clarity. B. Sagittal section through the anal canal: the anal canal is angled posteriorly and so anterior sphincteric structures appear to be lower than posterior structures. The glandular, vascular and fibromuscular structures and the conjoint longitudinal coat have been omitted for clarity.

**Middle rectal veins**

The middle rectal veins pass alongside the middle rectal arteries to drain into the anterior division of the internal iliac vein on the lateral wall of the pelvis.

**Lymphatics**

Lymphatics draining the rectum and the upper anal canal above the level of the dentate line pass superiorly, initially through the rectal wall, and then as a fine network over the surface of the rectum, before draining into nodes which lie in the loose adipose connective tissue of the mesorectum. Epirectal nodes lie very close to the
outer fibres of the rectal longitudinal muscle while pararectal nodes lie within the mesorectum, a variable distance from the rectal wall. The overall direction of drainage is upwards along the branches of the superior rectal artery. Drainage to intermediate groups occurs up to the nodes near the origin of the inferior mesenteric artery (Fig. 67.42).

Fig. 67.42  Lymph nodes of the rectum and upper anal canal (viewed from behind).
INNERVATION

The sympathetic supply to the rectum and upper anal canal originates in the first and second lumbar spinal segments. The fibres are distributed via the lumbar splanchnic nerves through the inferior mesenteric plexuses and via the sacral splanchnic nerves through the superior and inferior hypogastric plexuses: postganglionic axons reach the gut wall via periarterial plexuses on branches of the superior and middle rectal arteries, and are inhibitory to the muscle of the rectal wall.

The preganglionic parasympathetic supply to the rectum and upper anal canal is mediated via the pelvic splanchnic nerves, which travel through the inferior and superior hypogastric plexuses and along the nerve plexuses on the branches of the inferior mesenteric artery. Parasympathetic nerves are secretomotor to the colorectal glands, and motor to the rectal musculature, causing relaxation of the internal anal sphincter. Afferent impulses mediating sensations of distension are carried by visceral afferent fibres which travel with the parasympathetic nerves. Pain impulses pass in visceral afferents travelling with the sympathetic and parasympathetic nerves that supply the rectum and the upper part of the anal canal.

The role of rectal innervation in anorectal function and continence is described below.
ANAL CANAL

The anal canal begins at the anorectal junction and ends at the anal verge (Figs 67.43–67.45). It is angulated in relation to the rectum because the pull of the sling-like puborectalis produces the anorectal angle. It lies 2–3 cm in front of and slightly below the tip of the coccyx, which is opposite the apex of the prostate in males. The anal verge is marked by a sharp turn where the squamous epithelium which lines the lower anal canal becomes continuous with the skin of the perineum. The pigmentation of skin around the anal verge approximately corresponds to the extent of the external sphincter. Identification of the anal verge may be difficult, particularly in males in whom the perineum may ‘funnel’ upwards into the lower anal canal, however, the characteristic puckering of the external epithelium caused by the penetrating fibres of the conjoint longitudinal layer makes a useful landmark. The functional anal canal is represented by a zone of high pressure which roughly equates to the anatomical canal. The anal canal consists of an inner epithelial lining, a vascular subepithelium, the internal and external anal sphincters and fibromuscular supporting tissue as well as dense neuronal networks of both autonomic and somatic origin. It is between 2.5 and 5 cm long in adults although the anterior wall is slightly shorter than the posterior. It is usually shorter in females. At rest it forms an oval slit in the anteroposterior plane rather than a circular canal: the arrangement of the external anal sphincter and its attachments to the perineal body and coccyx create sites of maximum pressure within the anal canal in the anterior and posterior midline.
**Fig. 67.44** A, Mid-coronal MRI endocoil image of the anal canal. B, Anterior coronal MRI endocoil section in a woman showing the transverse perineii (TP) joining the external anal sphincter anteriorly (between arrows). EAS, external anal sphincter; IAS, internal anal sphincter; PR, puborectalis.
Anteriorly, the middle third of the anal canal is attached by dense connective tissue to the perineal body, which separates it from the membranous urethra and penile bulb in males or from the lower vagina in females. Laterally and posteriorly, the anal canal is surrounded by loose adipose tissue within the ischio-anal fossae; this offers a potential pathway for the spread of perianal sepsis from one side to the other (see Ch. 63). Posteriorly, the anal canal is attached to the coccyx by the anococcygeal ligament, a midline fibroelastic structure which may possess some skeletal muscle elements, and which runs between the posterior aspect of the middle portion of the external sphincter and the coccyx. Just above this is the raphe of the levator ani 'plate', the fusion of the two halves of iliococcygeus, which merges anteriorly with puborectalis. Between these two structures is a potential 'postanal' space.
The ischial spines may be palpated laterally by an examining finger in the upper anal canal. The pudendal nerves pass over the ischial spines at this point and pudendal nerve motor terminal latency may be measured digitally using a modified electrode worn on the examining glove.

**LINING OF THE ANAL CANAL**

The upper portion of the anal canal is lined by columnar epithelium similar to that of the rectum. It contains secretory and absorptive cells with numerous tubular glands or crypts. The subepithelial tissues are mobile and relatively distensible and possess profuse submucosal arterial and venous plexuses. Terminal branches of the superior rectal vessels pass downwards towards the anal columns. The submucosal veins drain into the submucosal rectal venous plexus and also through the fibres of the upper internal anal sphincter into an intermuscular venous plexus.

There are 6–10 vertical folds, the anal columns, in the mid anal canal. They tend to be obvious in children but less well-defined in adults. Each column contains a terminal radicle of the superior rectal artery and vein: the vessels are largest in the left-lateral, right-posterior and right-anterior quadrants of the wall of the canal where the subepithelial tissues expand into three ‘anal cushions’ (Fig. 67.46). The cushions help to seal the anal canal, to maintain continence to flatus and fluid, and are also important in the pathogenesis of haemorrhoids. The lower ends of the columns may form small crescentic folds, called the anal valves, between which lie small recesses referred to as anal sinuses. The anal valves and sinuses together form the dentate (or pectinate) line. About six anal glands open into small depressions, anal crypts, in the anal valves. The glands are branched and lined by stratified columnar epithelium. Cystic dilatations in the glands may extend through the internal sphincter and even into the external sphincter (Seow-Cheon & Ho 1994).
The mucosa below the dentate line is smooth, and termed the pectin. It is non-keratinized stratified squamous epithelium which lacks sweat and sebaceous glands and hair follicles, but contains numerous somatic nerve endings. It extends down to the intersphincteric groove, a depression at the lower border of the internal sphincter. The canal below the intersphincteric groove is lined by hair-bearing, keratinizing stratified epithelium which is continuous with the perianal skin. The submucosa below contains profuse arterial and venous plexuses and has more connective tissue than the upper canal. It may be tethered to fibres of the conjoint longitudinal layer of the intersphincteric groove.

The junction between the columnar and squamous epithelia is referred to as the anal transition zone (ATZ). It is variable in height and position and often contains islands of squamous epithelium extending up into the columnar mucosa; it is not the same as the dentate line which is an indistinct line observed in the anal canal. Nerve endings including thermoreceptors exist in the submucosa around the upper ATZ; they probably play a role in continence by providing a highly specialized ‘sampling’ mechanism to identify the contents of the lower rectum when the upper anal canal relaxes to allow rectal contents to come into contact with the upper anal canal epithelium (Duthie & Gairns 1960).

The well-defined muscularis mucosae of the rectum continues into the upper canal. Fibres from the longitudinal muscle pass through the internal sphincter and surround the submucosal venous plexus before turning upwards to merge with the muscularis mucosae and form the musculus submucosae ani.

Haemorrhoids

Haemorrhoids represent abnormal enlargement of the anal cushions. The partial drainage of the venous plexus into the intermuscular plane may play a role in this chronic engorgement as a result of obstruction of the venous flow during prolonged straining and defecation. Since the subepithelial vascular cushions of the upper, mid and lower anal canal form a continuous plexus, the differentiation of haemorrhoids into ‘internal’ and ‘external’ is somewhat arbitrary. The laxity of the upper anal canal submucosa is probably responsible for the fact that internal haemorrhoids may form more easily, although engorgement of the plexus deep to the lower anal epithelium may also occur. Since the epithelium in the lower canal is well supplied with sensory
nerve endings, acute distension or invasive treatment to haemorrhoids in this area causes profound discomfort, whereas invasive or destructive therapy with relatively few symptoms is possible in the upper canal because the latter is lined with insensate columnar mucosa.

**Anal fissures**

Acute, transient, vertical breaks in the anal epithelium are not uncommon. The development of chronic, non-healing fissures is less common. They are more likely to develop in the anterior, and particularly the posterior, midline of the anus, possibly because stress within the anal canal is concentrated in these regions by the arrangement of the fibres of the external sphincter: the relative paucity of the arterial supply in these regions probably contributes to poor healing. Persistent hypertonicity of the anal sphincter is a primary pathogenic factor, possibly developing as a consequence of disordered local reflex mechanisms between the lower rectum and internal anal sphincter.

**Cryptoglandular sepsis and fistula in ano**

Infection of the anal glands is the main cause of anal sepsis and cryptogenic fistula formation (Parks et al 1976). Because many of these glands extend into the intersphincteric plane, so-called cryptoglandular sepsis may readily spread into the same plane. The commonest route of drainage of this sepsis is downwards between the internal and external anal sphincters, appearing beneath the skin at the anal verge. Rupture or drainage of the sepsis at this point will form a fistula in ano in the intersphincteric plane. Less commonly, the infection drains outwards from the intersphincteric plane and passes through the fibres of the external anal sphincter, possibly along the spreading septa of the conjoint longitudinal coat, and appears in the perianal skin outside the external anal sphincter as a transphincteric fistula. If the sepsis does not originate in the intersphincteric plane, drainage is likely to be beneath the anal mucosa alone and a submucous fistula forms. Sepsis within the ischio-anal fossa surrounding the lower anal canal can spread with relative ease because the connective tissue is mostly loose adipose tissue. Pus may spread posteriorly, behind the lower anal canal into the contralateral ischio-anal fossa, because the lower anal canal lacks any ligamentous attachments (Parkes 1961).
MUSCLES OF THE ANAL CANAL

The anal canal is encircled by internal and external anal sphincters, separated by the longitudinal layer, and has connections superiorly to puborectalis and the transverse perinei (Fig. 67.47).

Fig. 67.47 A–C, Axial views of the anal canal at three levels on endoanal ultrasound in a woman. The endoanal ultrasound probe is the central black structure. A, Upper anal canal. The ‘U’ shape of puborectalis (PR) is visible. Ias, internal anal sphincter. B, Middle anal canal. The external anal sphincter (Eas) is now a complete ring anteriorly (arrowhead). Lm, longitudinal muscle; S, subepithelial tissues. C, Lower anal canal. Below the termination of the internal anal sphincter, the longitudinal layer extends through the subcutaneous external anal sphincter (between arrowheads). D–F, MRI of the anal canal. D, At upper anal canal level, the sling of puborectalis (PR) extends anteriorly to the pubic bones. Vag, vagina; Ur, urethra. E, At mid anal canal level.
Internal anal sphincter

The internal anal sphincter is a well-defined ring of obliquely orientated smooth muscle fibres that is continuous with the circular muscle of the rectum, and which terminates at the junction of the superficial and subcutaneous components of the external sphincter. Its thickness varies between 1.5 and 3.5 mm, depending upon the height within the anal canal and whether the canal is distended. It is usually thinner in females and becomes thicker with age. It may also be thickened in disease processes such as rectal prolapse and chronic constipation. The lower portion of the sphincter is crossed by fibres from the conjoint longitudinal coat which pass into the submucosa of the lower canal.

Vascular supply

The internal anal sphincter is supplied from the terminal branches of the superior rectal vessels and branches of the inferior rectal vessels.

Innervation

The internal anal sphincter is supplied by the sympathetic and parasympathetic systems by fibres that extend down from the lower rectum. Sympathetic fibres originate in the lower two lumbar spinal segments, are distributed via the inferior hypogastric plexus, and cause contraction of the sphincter. Parasympathetic fibres originate in the second to fourth sacral spinal segments, are distributed via the inferior hypogastric plexus, and cause relaxation of the sphincter.

External anal sphincter

The external anal sphincter is an oval tube-shaped complex of striated muscle, composed mainly of type 1 (slow twitch) skeletal muscle fibres, which are well suited to prolonged contraction. It has been described as consisting of deep, superficial and subcutaneous parts but the external anal sphincter should be considered as a single functional and anatomical entity although the upper middle and lower thirds show different features and attachments. Endoanal ultrasound and magnetic resonance imaging reveal that the uppermost fibres blend with the lowest fibres of puborectalis. In the upper third some of these upper fibres decussate anteriorly into the superficial transverse perineal muscles and posteriorly some fibres are attached to the anococcygeal raphe. The majority of the fibres of the middle
third of the external anal sphincter surround the lower part of the internal sphincter. The middle third is attached anteriorly to the perineal body and posteriorly to the coccyx via the anococcygeal ligament: some fibres from each side of the sphincter decussate in these areas to form a commissure in the anterior and posterior midline. The fibres of the lower third lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium by submucosa.

The length and thickness of the external anal sphincter varies between the sexes. In females, the anterior portion tends to be shorter, the wall may be slightly thinner, and the tube may take the form of an asymmetrical cone (Rociu et al 2000) and the transverse perineii and bulbospongiosus fuse with the external sphincter in the lower part of the perineum. In males, the external sphincter is more anular and is separate from the central point of the perineum into which the transverse perineii and bulbospongiosus fuse, so that there is a surgical plane of cleavage between the external sphincter and perineum (Fig. 67.48).
Fig. 67.48  Typical anatomy of male and female external anal sphincters. Puborectalis is shown in isolation with the external anal sphincter viewed from the superolateral aspect. The anterior portion of the external anal sphincter is typically shorter and thinner in females.

**Vascular supply**

The external anal sphincter is supplied from the terminal branches of the inferior rectal vessels with a small contribution from the median sacral artery.

**Innervation**
The external anal sphincter is innervated mainly by the inferior rectal branch of the pudendal nerve (anterior divisions of the second, third and fourth sacral spinal nerves). It may also receive some direct supply via fibres which leave the ventral rami of these nerves as they exit the sacral foramina and run beneath the fascia over levator ani to reach the anorectal junction.
FIBROMUSCULAR STRUCTURES OF THE ANAL CANAL

Longitudinal layer and conjoint longitudinal coat

The longitudinal layer is situated between the internal and external sphincters. It contains a fibromuscular layer, the conjoint longitudinal coat, and the intersphincteric space with its connective tissue components (Lunniss & Phillips 1992). The longitudinal layer has muscular and fibroelastic components. The muscular element is formed by fusion of striated muscle fibres from puboanalis, which is the innermost part of puborectalis, with smooth muscle from the longitudinal muscle of the rectum. Endoanal ultrasound and magnetic resonance imaging demonstrate either bundles or incomplete sheets of muscle extending down between the sphincters in the upper canal in both sexes: in men these often end just above the lower border of the internal sphincter. The layer then becomes completely fibroelastic, and splits into septa running between bundles of the subcutaneous external sphincter to terminate in the perianal skin. The area bounded by these septa is generally referred to as the perianal space. The most peripheral of the septa extend between the fibres of the external sphincter into the ischio-anal fat. The most central septa pass through the fibres of the internal sphincter to reach the anal lining and may help to form the intersphincteric groove. The conjoint longitudinal coat is innervated by autonomic fibres that share an origin with the fibres that innervate the internal sphincter.

Other fibromuscular structures

A layer of smooth muscle, yellow elastic fibres, and collagenous connective tissue is found in the anal submucosa, inferior to the anal sinuses. It is derived mainly from strands of the conjoint longitudinal coat, which descend inwards between the fibres of the internal sphincter. Some of the strands end by turning outwards around the lower edge of the internal sphincter to rejoin the main longitudinal layer. Most continue obliquely downwards and insert into the dermis below the intersphincteric groove. These attachments may help to form the corrugations seen in the perianal skin. The septa end in a honeycomb-like arrangement of fibres, which prevents easy distension of the lowest anal lining. This may explain the severe pain produced by pus or blood which collects here, since small volumes of fluid rapidly produce high pressure within the subepithelium.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The arterial supply to the anal canal is derived from terminal branches of the superior rectal artery, the inferior rectal branch of the pudendal artery and branches of the median sacral artery. The supply to the anal canal lining is not distributed uniformly. The arterial supply of the anterior and, more particularly, the posterior, midline epithelia is less good than that lining the lateral portions of the canal (Klosterhalfen et al 1989), which is relevant to the perpetuation of chronic anal fissures.

Veins

The venous drainage of the upper anal canal mucosa, internal anal sphincter and conjoint longitudinal coat passes via the terminal branches of the superior rectal veins into the inferior mesenteric vein. The lower anal canal and external sphincter drain via the inferior rectal branch of the pudendal vein into the internal iliac vein.

Lymphatics

Lymphatics from the upper anal mucosa, internal anal sphincter and conjoint longitudinal coat drain upwards into the submucosal and intramural lymphatics of the rectum. The lower anal canal epithelium and external anal sphincter lymphatics drain downwards via perianal plexuses into vessels that drain into the external inguinal lymph nodes. The lymphatics of puborectalis drain into the internal iliac lymph nodes. This arrangement has considerable importance for tumours of the lower rectum and upper anal canal. If the tumour is confined to the tissue of origin, malignant spread is confined to the mesorectal lymph nodes. However, if the tumour involves puborectalis or tissues associated with the external anal sphincter, the possibility of lymph node spread to these other groups may require radical excision and much more extensive surgery.
INNERVATION

The anal canal is innervated by both autonomic and somatic nervous systems. Preganglionic sympathetic fibres originate in the lower two lumbar segments, run via the lumbar sympathetic chain into the upper two sacral sympathetic ganglia, and into the inferior hypogastric plexus via the sacral splanchnic nerves. Parasympathetic fibres originate in the second to fourth sacral spinal segments and also run to the inferior hypogastric plexus via the pelvic splanchnic nerves. From the inferior hypogastric plexus both sympathetic and parasympathetic fibres run together in nerves of the 'pelvic plexus' and enter the lower rectal wall via the 'lateral ligaments' of the rectum and anorectal junction via the endopelvic fascia over levator ani. They are distributed to the submucosal and myenteric plexuses where most fibres terminate on interstitial cells (of Cajal).

The autonomic supply to the anus innervates the upper anal mucosa (rich in thermoreceptors), the internal anal sphincter and the conjoint longitudinal coat. Sympathetic fibres cause relaxation of the lower rectal muscle but contraction of the conjointed longitudinal coat and internal anal sphincter fibres via α-adrenergic receptors. Parasympathetic fibres cause relaxation of the internal sphincter via muscarinic receptors which stimulate release of nitric oxide from intramural nitrergic neurones (Brading & Ramalingam 2006).

The external anal sphincter and lower half of the anal mucosa and perianal skin (which are both rich in nocioceptors and pressure receptors) receive a somatic innervation from the anterior divisions of the second, third and fourth sacral spinal nerves which is mainly distributed via the inferior rectal branch of the pudendal nerve. There may also be some direct supply via fibres which leave the ventral rami of the second to fourth sacral nerves as they exit the sacral foramina and run beneath the fascia over levator ani to reach the anorectal junction (because some somatic reflexes are not abolished by division of the pudendal nerves).

Referred pain

Pain in the lower two thirds of the anus is usually felt with a high degree of acuity and is well localized to the perineum and anal canal itself.

Reflexes, control of anorectal function and continence

Local reflex arcs exist within the anorectal intramural plexuses and also within the sacral segments of the spinal cord a spinal centre for co-ordination of anorectal function has not yet been identified. These reflex arcs involve both autonomic and somatic elements because the co-ordination of continence and the initiation of defecation requires that the lower rectum, internal and external anal sphincters act together.
The internal anal sphincter often relaxes following distension of the rectum (Recto-Anal Inhibitory Reflex or ‘RAIR’), suggesting that local reflex pathways exist between the lower rectal sensory fibres and sphincteric motor fibres. This relaxation also occurs on stimulation of somatic sensory nerves, even after the rectum has been excised completely, and is presumably mediated via proprioceptors present in the pelvic floor and an additional reflex pathway via the sacral spinal segments. Integrating the sensory input from the anal canal so as to control the activity of the anal musculature occurs at many levels in the nervous system, including the spinal cord, brain stem, thalamus and cortex. Neural activity not only monitors and regulates defecation, but also other more subtle behaviours within the rectum and anal canal, such as the separation of faeces from rectal gas; local adjustments to faecal consistency and quantities; self-cleansing movements in the rectum and anal canal; coordination with other actions of the perineal and abdominal muscles.

To keep the anal canal closed, the pressure within the anal canal has to be higher than that in the rectum. The resting pressure in the canal is maintained mainly by tonic activity of the internal sphincter as a result of sympathetic tone: sudden increases of intrarectal pressure, e.g. during coughing or exertion, are compensated for by rapid contraction of the external sphincter and puborectalis via spinal reflexes. Angulation of the anorectal junction and the ‘flap valve’ theory is no longer considered important in continence since dynamic imaging of the process of defecation (proctography) has demonstrated that there is a wide range of angulation which does not correlate with function. The internal sphincter does not close the canal completely; the gap (approximately 7 mm) is sealed by the distensible, vascular subepithelial tissues.

Defecation

Defecation is a conscious physiological act in response to feeling the need to pass stool in the rectum: it requires coordinated relaxation of the pelvic floor muscles and anal sphincter. The dynamics have been studied using pressure measurements in the colon, rectum and anus (Herbst et al 1997), and by various imaging techniques including fluoroscopy, ultrasonography and magnetic resonance imaging (Kruyt et al 1991). The process is initiated by mass colonic contractions which drive faeces into the rectum. Rectal distension occurs progressively; there is little increase in intra-rectal pressure because the rectal musculature relaxes as a result of either local intramural or spinal reflexes mediated via sympathetic and parasympathetic fibres. The RAIR is probably involved in allowing the descent of rectal contents into the upper anal canal where it can be ‘sampled’ by contact with the mucosal receptors (particularly thermoreceptors). Defecation may be deferred by conscious contraction of the external anal sphincter until contractions cease and retrograde rectal peristalsis moves stool out of the distal rectum, so that the sensation to defecate passes off. Initiation of defecation involves
conscious relaxation of the pelvic floor muscles and external sphincter, so that the pelvic floor descends slightly allowing the anorectal angle to straighten. Reflex relaxation of the internal anal sphincter and conjoint longitudinal coat allows the anal canal to open. Abdominal muscle contraction will aid expulsion from the rectum, but continuing mass colonic contractions push more faeces down into the rectum, so that the entire left colon may be emptied.

Anorectal incontinence

Anal incontinence is common and may occur for a variety of reasons. Abnormally high rectal pressures, as occur in severe diarrhoea, may overcome a normal sphincter, and autonomic disorders may produce abnormal motor activity or loss of normal sensation, so that there is no awareness of the presence of stool. Damage to the anal sphincter may result from vaginal delivery due to stretch, instrumentation or surgical procedures. Atrophy of the external sphincter may occur secondary to pudendal nerve damage during delivery (and may also occur in diabetics, neurological disease and the elderly) A damaged sphincter will not be able to overcome normal fluctuations of intrarectal pressures, or there may be a combination of damage and rectal dysfunction resulting in anal incontinence.
MICROSTRUCTURE

The layers of tissue in the large intestinal wall (see Fig. 67.3; Fig. 67.49) resemble those in the small intestine (Ch. 66), except that villi and circular folds are absent and the glands (crypts) are longer.

![Diagram](image)

**Fig. 67.49** The microstructure of the colonic wall and its epithelial cells. Note the aggregations of lymphocytes (blue) and undifferentiated epithelial cells (white).

Mucosa

The mucosa is pale, smooth, and, in the colon, raised into numerous crescent-shaped folds between the sacculi. In the rectum it is thicker, darker, more vascular, and more loosely attached to the submucosa.

Epithelium

The luminal surface of all but the anorectal junction is lined by columnar cells, mucous (goblet) cells, and occasional microfold (M) cells that are restricted to the epithelium overlying lymphoid follicles. Columnar and mucous cells are also present in the intestinal glands (crypts) which additionally contain stem cells and neuroendocrine cells. In general, the glands lack Paneth cells, but some may be present in the caecum.

Columnar (absorptive) cells
Columnar (absorptive) cells are the most numerous of the epithelial cell types. They are responsible for ion exchange and other transepithelial transport functions including water resorption, particularly in the colon. Although there is some variation in their structure, they all bear apical microvilli, which are shorter and less regular than those on enterocytes in the small intestine. All cells have typical junctional complexes around their apices, and these limit extracellular diffusion from the lumen across the intestine wall.

Mucous (goblet) cells

Mucous cells have a similar structure to those of the small intestine, but are more numerous. They are outnumbered by absorptive cells for most of the length of the colon, but they are equally frequent towards the rectum, where their numbers increase further.

Microfold (M) cells

Microfold cells are similar to those of the small intestine: they are flattened or cuboidal cells with long, blunt microfolds rather than typical microvilli, and they are restricted to epithelium overlying lymphoid follicles.

Stem cells

Stem cells are the source of the other epithelial cell types in the large intestine. They are located at or near the bases of the intestinal glands, where they divide by mitosis. They provide cells that migrate towards the luminal surface of the intestine: their progeny differentiate, undergo apoptosis and are shed after approximately 5 days.

Neuroendocrine cells

Neuroendocrine cells are situated mainly at the bases of the glands, and secrete basally into the lamina propria.

Intestinal glands (crypts)

The crypts are narrow perpendicular tubular glands which are longer, more numerous and closer together than those of the small intestine. Their openings give a cribriform appearance to the mucosa in surface view. The glands are lined by low columnar epithelial cells, mainly goblet cells, between which are columnar absorptive cells and neuroendocrine cells. Epithelial stem cells at their bases give rise to all three cell types.

Lamina propria

The lamina propria is composed of connective tissue that supports the epithelium. It forms a specialized pericryptal myofibroblast sheath around each intestinal gland. Solitary lymphoid follicles within the lamina propria are most abundant in the caecum, appendix and rectum, but are also present scattered along the rest of the large intestine. They are similar to those of the small intestine; efferent lymphatic vessels originate within them. Lymphatic vessels are absent from the lamina propria core between crypts.

Muscularis mucosae
The muscularis mucosae of the large intestine is essentially similar to that of the small intestine: it has prominent longitudinal and circular layers.

**Submucosa**

The submucosa of the large intestine is similar to that of the small intestine.

**Muscularis externa**

The muscularis externa has outer longitudinal and inner circular layers of smooth muscle. The longitudinal fibres form a continuous layer but, with the exception of the uniform outer muscle layer of most of the appendix, macroscopically these are aggregated as longitudinal bands or taeniae coli (see Figs 67.3 and 67.12). Between the taeniae coli the longitudinal layer is much thinner, less than half the circular layer in thickness. The circular fibres form a thin layer over the caecum and colon, and are aggregated particularly in the intervals between the sacculi. In the rectum they form a thick layer and in the anal canal they form the internal anal sphincter. There is an interchange of fascicles between circular and longitudinal layers, especially near the taeniae coli. Deviation of longitudinal fibres from the taeniae to the circular layer may, in some instances, explain the haustration of the colon.

**Serosa**

The serosa or visceral peritoneum is variable in extent. Along the colon the peritoneum forms small fat-filled appendices epiploicae which are most numerous on the sigmoid and transverse colon but generally absent from the rectum. Subserous loose connective tissue attaches the peritoneum to the muscularis externa.

CHAPTER 68 – Liver

The liver is the largest of the abdominal viscera, occupying a substantial portion of the upper abdominal cavity. It occupies most of the right hypochondrium and epigastrium, and frequently extends into the left hypochondrium as far as the left lateral line (Fig. 68.1). As the body grows from infancy to adulthood the liver rapidly increases in size. This period of growth reaches a plateau around 18 years and is followed by a gradual decrease in the liver weight from middle age. The ratio of liver to body weight decreases with growth from infancy to adulthood. The liver weighs approximately 5% of the body weight in infancy and it decreases to approximately 2% in adulthood. The size of the liver also varies according to sex, age and body size. It has an overall wedge shape, which is in part determined by the form of the upper abdominal cavity into which it grows. The narrow end of the wedge lies towards the left hypochondrium, and the anterior edge points anteriorly and inferiorly. The superior and right lateral aspects are shaped by the anterolateral abdominal and chest wall as well as the diaphragm. The inferior aspect is shaped by the adjacent viscera. The capsule is no longer thought to play an important part in maintaining the integrity of the shape of the liver.

Throughout life the liver is reddish brown in colour, although this can vary depending upon the fat content. Obesity is the most common cause of excess fat in the liver (also known as steatosis): the liver assumes a more yellowish tinge as its fat content increases. The texture is usually soft to firm, although it depends partly on the volume of blood the liver contains and the fat content.

The liver performs a wide range of metabolic activities required for homeostasis, nutrition and immune defence. For example, it is important in the removal and breakdown of toxic, or potentially toxic, materials from the blood and the regulation of blood glucose and lipids, the storage of certain vitamins, iron, and other micronutrients, and in breaking down or modifying amino acids. It is involved in a plethora of other biochemical reactions. Since the majority of these processes are exothermic, a substantial part of the thermal energy production of the body, especially at rest, is provided by the liver. The liver is populated by phagocytic macrophages, components of the mononuclear phagocyte system capable of removing particulates from the blood stream. It is an important site of haemopoiesis in the fetus.
SURFACES OF THE LIVER

The liver is usually described as having superior, anterior, right, posterior and inferior surfaces, and has a distinct inferior border (Figs 68.2, 68.3). However, the superior, anterior and right surfaces are continuous and no definable borders separate them. It would be more appropriate to group them as the diaphragmatic surface, which is mostly separated from the inferior, or visceral surface, by a narrow inferior border. At the infrasternal angle the inferior border is related to the anterior abdominal wall and is accessible to examination by percussion, but is not usually palpable. In the midline, the inferior border of the liver is near the transpyloric plane, about a hand's breadth below the xiphisternal joint. In women and children the border often projects a little below the right costal margin.
Superior surface

The superior surface is the largest surface and lies immediately below the diaphragm, separated from it by peritoneum except for a small triangular area where the two layers of the falciform ligament diverge. The majority of the superior surface lies beneath the right dome, but there is a shallow cardiac impression centrally that corresponds to the position of the heart above the central tendon of the diaphragm. The left side of the superior surface lies beneath part of the left dome of the diaphragm.

Anterior surface

The anterior surface is approximately triangular and convex and is covered by peritoneum except at the attachment of the falciform ligament. Much of it is in contact with the anterior attachment of the diaphragm. On the right the diaphragm separates it from the pleura and sixth to tenth ribs and cartilages, and on the left from the seventh and eighth costal cartilages.

Right surface
The right surface is covered by peritoneum and lies adjacent to the right dome of the diaphragm which separates it from the right lung and pleura and the seventh to 11th ribs. The right lung and basal pleura both lie above and lateral to its upper third, between the diaphragm and the seventh and eighth ribs. The diaphragm, the costodiaphragmatic recess lined by pleura, and the ninth and tenth ribs all lie lateral to the middle third of the right surface. Lateral to the lower third, the diaphragm and thoracic wall are in direct contact. Rarely, the hepatic flexure and proximal transverse colon may lie on a long mesentery over the right and superior surfaces of the liver, referred to as Chilaiditi syndrome.

Posterior surface

The posterior surface is convex, wide on the right, but narrow on the left. A deep median concavity corresponds to the forward convexity of the vertebral column close to the attachment of the ligamentum venosum. Much of the posterior surface is attached to the diaphragm by loose connective tissue, forming the triangular ‘bare area’. The inferior vena cava lies in a groove or tunnel in the medial end of the ‘bare area’. To the left of the caval groove the posterior surface of the liver is formed by the caudate lobe, and covered by a layer of peritoneum continuous with that of the inferior layer of the coronary ligament and the layers of the lesser omentum. The caudate lobe is related to the diaphragmatic crura above the aortic opening and the right inferior phrenic artery, and separated by these structures from the descending thoracic aorta.

The fissure for the ligamentum venosum separates the posterior aspect of the caudate lobe from the main part of the left lobe. The fissure cuts deeply in front of the caudate lobe and contains the two layers of the lesser omentum. The posterior surface over the left lobe bears a shallow impression near the upper end of the fissure for the ligamentum venosum that is caused by the abdominal part of the oesophagus. The posterior surface of the left lobe to the left of this impression is related to part of the fundus of the stomach. Together these posterior relations make up what is sometimes referred to as the ‘bed’ of the liver (Fig. 68.1).

Inferior surface

The inferior surface is bounded by the inferior edge of the liver. It blends with the posterior surface in the region of the origin of the lesser omentum, the porta hepatis and the lower layer of the coronary ligament, and is marked near the midline by a sharp fissure which contains the ligamentum teres (the obliterated fetal left umbilical vein). The gallbladder usually lies in a shallow fossa, but this is variable: it may have a short mesentery or be completely intrahepatic and lie within a cleft in the liver parenchyma. The quadrate lobe lies between the fissure for the ligamentum teres and the gallbladder.

The inferior surface of the left lobe is related inferiorly to the fundus of the stomach and the upper lesser omentum. The quadrate lobe lies adjacent to the pylorus, first part of the duodenum and the lower part of the lesser omentum. Occasionally the transverse colon lies between the duodenum and the quadrate lobe. To the right of the gallbladder, the inferior surface is related to the hepatic flexure of the colon, the right suprarenal gland and right kidney, and the first part of the duodenum.
GROSS ANATOMICAL LOBES

Historically, the liver has been considered to be divided into right, left, caudate and quadrate lobes by the surface peritoneal and ligamentous attachments.

Right lobe

The right lobe is the largest in volume and contributes to all surfaces of the liver. It is divided from the left lobe by the falciform ligament superiorly and the ligamentum venosum inferiorly. On the inferior face to the right of the groove formed by the ligamentum venosum there are two prominences separated by the porta hepatis: the caudate lobe lies posterior, and the quadrate lobe anterior, to the porta hepatis. The gallbladder lies in a shallow fossa to the right of the quadrate lobe.

Left lobe

The left lobe is the smaller of the two main lobes, although it is nearly as large as the right lobe in young children.

It lies to the left of the falciform ligament with no subdivisions, and is substantially thinner than the right lobe, having a thin apex that points into the left upper quadrant.

Quadrate lobe

The quadrate lobe is visible as a prominence on the inferior surface of the liver, to the right of the groove formed by the ligamentum venosum (and thus is incorrectly said to arise from the right lobe although it is functionally related to the left lobe). It lies anterior to the porta hepatis and is bounded by the gallbladder fossa to the right, a short portion of the inferior border anteriorly, the fissure for the ligamentum teres to the left, and the porta hepatis posteriorly.

Caudate lobe

The caudate lobe is visible as a prominence on the inferior and posterior surfaces to the right of the groove formed by the ligamentum venosum: it lies posterior to the porta hepatis. To its right is the groove for the inferior vena cava. Above, it continues into the superior surface on the right of the upper end of the fissure for the ligamentum venosum. In gross anatomical descriptions this lobe is said to arise from the right lobe, but it is functionally separate.
FUNCTIONAL ANATOMICAL DIVISIONS

Current understanding of the functional anatomy of the liver is based on Couinaud’s division of the liver into eight (subsequently nine) functional segments, based upon the distribution of portal venous branches and the location of the hepatic veins in the parenchyma (Couinaud 1957). Further understanding of the intrahepatic biliary anatomy, especially of the right ductal system, was enhanced by contributions from Hjortsjö (1948) and Healey & Schroy (1953) using the biliary system as the main guide for division of the liver (Fig. 68.4).

![Diagram of liver divisions](image)

**Fig. 68.4** The fissures and sectors of the liver. (Right lateral = right posterior; right medial = right anterior.)

The liver is divided into four portal sectors by the four main branches of the portal vein. These are right lateral, right medial, left medial and left lateral (sometimes the term posterior is used in place of lateral and anterior in place of medial). The three main hepatic veins lie between these sectors as intersectorial veins. These intersectoral planes are also called portal fissures (scissures). The fissures containing portal pedicles are called hepatic fissures. Each sector is sub-divided into segments (usually two) based on their supply by tertiary divisions of the vascular biliary sheaths.

**Fissures of the liver**

Knowledge of the fissures of the liver is essential for understanding liver surgery. Three major fissures, not visible on the surface, run through the liver parenchyma and harbour the three main hepatic veins (main, left and right portal fissures). Three minor
fissures are visible as physical clefts of the liver surface (umbilical, venous and fissure of Gans).

Main portal fissure

The main fissure extends from the tip of the gallbladder back to the midpoint of the inferior vena cava and contains the middle (main) hepatic vein. It separates the liver into right and left hemi-livers. Segments V and VIII lie to the right and segment IV to the left of the fissure.

Left portal fissure

The left fissure divides the left hemi-liver into medial (anterior) and lateral (posterior) sectors. It extends from the mid point of the anterior edge of the liver between the falciform ligament and the left triangular ligament to the point which marks the confluence of the left and middle hepatic veins. It contains the left hepatic vein and separates the left anterior and left posterior sectors: segment III lies anteriorly and segment II posteriorly.

Right portal fissure

The right portal fissure divides the right hemi-liver into lateral (posterior) and medial (anterior) sectors. The plane of the right fissure is the most variable amongst the main fissures and runs approximately diagonally through the gross right lobe from the lateral end of the anterior border to the confluence of the left and middle hepatic veins. The fissure divides the right anterior sector to its left (segments V and VIII) from the right posterior sector to its right (segments VI and VII), and contains the right hepatic vein. The right fissure marks the thickest point of liver parenchyma which is commonly transected during liver resection.

Umbilical fissure

The umbilical fissure separates segment III from segment VI within the left anterior sector and contains a main branch of the left hepatic vein (the umbilical fissure vein). It is marked by the attachment of the falciform ligament and sometimes covered by a ridge of liver tissue extending between the segments: it is often avascular and can be divided safely with diathermy during a surgical approach. It contains the umbilical portion of the left portal vein and the final divisions of the left hepatic duct and the left hepatic artery branches. The umbilical portion of the left portal vein is an important landmark: access to this vein and mobilization of the left portal vein are essential steps in surgery for hilar cholangiocarcinoma. A knowledge of the arrangement of the portal vein, hepatic artery and bile duct within the umbilical fissure is also essential when splitting the liver for an adult and paediatric recipient and for live donor liver transplantation for a child recipient.

Venous fissure

The venous fissure is a continuation of the umbilical fissure on the under surface of the liver and contains the ligamentum venosum. It lies between the caudate lobe and segment IV. The deeper continuation of this plane is the dorsal fissure.

Fissure of Gans
The fissure of Gans lies on the undersurface of the right lobe of the liver behind the gallbladder fossa. It often contains the portal pedicle to the right posterior sector and is thought to correspond to the right fissure as it relates to the separation of the sectors of the liver.

**Sectors and segments of the liver**

**Sectors**

The sectors of the liver are made up of between one and three segments: right lateral sector = segments VI and VII; right medial sector = segments V and VIII; left medial sector = segments III and IV (and part of I); left lateral sector = segment II (Fig. 68.5). Segments are numbered in an ante-clockwise spiral centered on the portal vein with the liver viewed from beneath, starting with segment I up to segment VI, and then back clockwise for the most cranial two segments VII and VIII (Fig. 68.6).
Fig. 68.5  Segments of the liver (after Couinaud). A, superior view; B, posterior view; C, anterior view; D, inferior view. The segments are sometimes referred to by number (name) – I (caudate) (sometimes subdivided into left and right parts called segment IX); II (left lateral superior); III (left medial inferior); IV (left medial superior) (sometimes subdivided into superior and inferior parts); V (right medial inferior); VI (right lateral inferior); VII (right lateral superior); VIII (right medial superior).

Fig. 68.6  Segments of the liver seen on axial CT scan. A, Contrast enhanced CT shows the left (L), middle (M), and right (R) hepatic veins at the superior aspect of the liver marking the left main and right portal fissures. B, Inferior to this the caudate lobe (segment I) lies between the inferior vena cava (IVC) and the main portal vein (PV). The left portal vein (LPV) separates segment II superiority from segment III inferiorly. C, The right portal vein (RPV) divides segments V and VI inferiorly (C) from segments VII and VIII superiority (B).

Segment I
Segment I corresponds to the anatomical caudate lobe and lies posterior (dorsal) to segment IV with its left half directly posterior to segments II and III and its medial half surrounded by major vascular branches. The Glissonian sheaths to segment I arise from both right and left main sheaths: the segment therefore receives vessels independently from the left and right portal veins and hepatic arteries, and it drains independently into the inferior vena cava by multiple small branches (referred to as the lower group). They nearly always arise in the lower and occasionally from the middle third, but never from the upper third of the segment. The bile ducts draining the segment are closely related to the confluence of the right and left hepatic ducts such that excision of central bile duct tumours usually requires removal of segment IV.

Segment II

Segment II is the only segment in the left lateral sector of the liver and lies postero-lateral to the left fissure. It often has only one Glissonian sheath and drains into the left hepatic vein. Rarely, a separate vein drains directly into the inferior vena cava.

Segment III

Segment III lies between the umbilical fissure and the left fissure and is often supplied by one to three Glissonian sheaths: it drains into the left hepatic vein. The vein of the falciform ligament can provide an alternative drainage route for segment III.

Segment IV

Segment IV lies between the umbilical fissure and the main fissure, anterior to the dorsal fissure and segment I. Segment IV is supplied by three to five Glissonian sheaths, of which the majority arise in the umbilical fissure; their origins are often close to those that supply to segments II and III. Occasionally segment IV is supplied by branches from the main left pedicle. The main venous drainage segment is into the middle hepatic vein; the segment can also drain into the left hepatic vein through the vein of the falciform ligament.

Segment V

Segment V is the inferior segment of the right medial sector and lies between the middle and the right hepatic veins. Its size is variable, as are the number of Glissonian sheaths that supply it. Venous drainage is into the right and middle hepatic veins.

Segment VI

Segment VI forms the inferior part of the right lateral sector posterior to the right portal fissure. It is often supplied by two to three branches from the right posterior Glisson’s sheath, but occasionally the Glisson’s sheath to segment VI can arise directly from the right pedicle. Venous drainage is normally into the right hepatic vein, but may be via the right inferior hepatic vein directly into the inferior vena cava.

Segment VII

Segment VII forms the superior part of the posterior sector and lies behind the right hepatic vein. The sheaths to segment VII are often single. The venous drainage is into the right hepatic vein; occasionally the segment can drain through the right middle hepatic vein directly into the inferior vena cava.
Segment VIII

Segment VIII is the superior part of the right anterior sector. The right anterior sectoral sheaths end in segment VIII and supply it after giving off branches to segment V. The venous drainage is to the right and middle hepatic veins.

Segment IX

Segment IX is a recent subdivision of segment I, and describes that part of the segment that lies posterior to segment VIII.

Supports of the liver

The liver is stabilized and maintained in its position in the right upper quadrant of the abdomen by both static and dynamic factors. Richelme & Bourgeon (1973) suggested a three-tier classification of the anatomical factors: the suspensory attachments at the posterior abdominal wall to the inferior vena cava, hepatic veins, coronary and triangular ligaments (primary factors); the support provided by the right kidney, right colonic angle and duodenopancreatic complex (secondary factors); the attachment to the anterior abdominal wall and diaphragm by the falciform ligament (tertiary factors).

The surgical implications of these different factors are important for traumatologists in terms of achieving a better understanding of the pathophysiology of liver trauma. The inferior vena cava and the supra-hepatic veins, especially the right hepatic vein, appear to be the most important anatomical structures that support the bulk of the liver. Other factors which are responsible for the maintenance of the position of the liver within the abdominal cavity include positive intra-abdominal pressure and the movement of the diaphragm during respiration.

Peritoneal attachments and ligaments of the liver

The liver is attached to the anterior abdominal wall, diaphragm and other viscera by several ligaments which are formed from condensations of the peritoneum.

Falciform ligament

The liver is attached in front to the anterior abdominal wall by the falciform ligament. The two layers of this ligament descend from the posterior surface of the anterior abdominal wall and diaphragm and turn onto the anterior and superior surfaces of the liver. On the dome of the superior surface, the right leaf runs laterally and is continuous with the upper layer of the coronary ligament. The left layer of the falciform ligament turns medially and is continuous with the anterior layer of the left triangular ligament. The ligamentum teres, which represents the obliterated left umbilical vein, runs in the lower free border of the falciform ligament and continues into a fissure on the inferior surface of the liver. In fetal life the left umbilical vein opens into the left portal vein: it is supposed to be obliterated in adult life, but frequently remains partially patent. This lumen may open up in conditions such as portal hypertension to form a collateral channel. The ligamentum teres has importance in abdominal surgery for several reasons. It is quite often divided in upper abdominal surgery to optimize access to the upper abdominal viscera or as the first step in the mobilization of the liver. The ligament is vascularized by numerous arterial branches, mainly from the segment IV artery, and these form an anastomotic connection with the branches of...
the internal thoracic artery: it is therefore important to ligate or coagulate the ligament during its division. The ligamentum teres is a landmark and guide to the segment III hepatic duct used in hepatocojejunostomy formation, and to the left portal vein lying in the umbilical fissure during creation of a mesentericoportal shunt.

**Coronary ligament**

The coronary ligament is formed by the reflection of the peritoneum from the diaphragm onto the posterior surfaces of the right lobe of the liver. A large triangular area of liver devoid of peritoneal covering, the ‘bare area’ of the liver, is defined between the two layers of the coronary ligament. Here the liver is attached to the diaphragm by areolar tissue and is in continuity inferiorly with the anterior pararenal space. The coronary ligament is continuous on the right with the right triangular ligament. On the left, the two layers become closely applied, and form the left triangular ligament. The upper layer of the coronary ligament is reflected superiorly onto the inferior surface of the diaphragm and inferiorly onto the right and superior surface of the liver. The lower layer of the coronary ligament is reflected inferiorly over the right suprarenal gland and right kidney, and superiorly onto the inferior surface of the liver. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be brought forward, and exposes the lateral aspect of the inferior vena cava behind the liver.

**Triangular ligaments**

The left triangular ligament is a double layer of peritoneum which extends to a variable length over the superior border of the left lobe of the liver. Medially the anterior leaf is continuous with the left layer of the falciform ligament and the posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus, the upper end of the lesser omentum and part of the fundus of the stomach. Division of the left triangular ligament allows the left lobe of the liver to be mobilized for exposure of the abdominal oesophagus and crura of the diaphragm. The left triangular ligament is an important stabilizing factor for the left lobe in operations involving removal of the right lobe of the liver. Its division will result in the left lobe being unstable to the extent that it can rotate and displace into the space vacated under the right hemidiaphragm: this extreme degree of rotation can compromise the venous outflow of the liver with consequent liver dysfunction. If it is divided, the left triangular ligament must be fixed at the end of the surgery, in addition to fixing back the falciform ligament.

The right triangular ligament is a short structure which lies at the apex of the ‘bare area’ of the liver and is continuous with the layers of the coronary ligament.

**Lesser omentum**

The lesser omentum is a fold of peritoneum which extends from the lesser curve of the stomach and proximal duodenum to the inferior surface of the liver. Its attachment to the inferior surface of the liver is L-shaped. The vertical component follows the line of the fissure for the ligamentum venosum, the fibrous remnant of the ductus venosus. More inferiorly the attachment runs horizontally to complete the L in the porta hepatis. At its upper end, the superior layer of the lesser omentum is continuous on the left with the posterior layer of the left triangular ligament, and the inferior layer is continuous on the right with the coronary ligament as it encloses the inferior vena cava.
cava. At its lower end, the two layers diverge to surround the structures of the porta hepatis. A thin fibrous condensation of fascia usually runs from the medial end of the porta hepatis into the fissure in the inferior surface which contains the ligamentum teres. This fascia is continuous with the lower border of the falciform ligament when the ligamentum teres re-emerges at the inferior border of the liver. Care should be taken when dividing the lesser omentum, because an aberrant left hepatic artery may run in the medial end: when present, it invariably extends to the liver at the base of the umbilical fissure, and may be identified by a pulsation in the lesser omentum close to the umbilical fissure.

**Ligamentum venosum**

The ligamentum venosum represents the obliterated venous connection that existed between the left portal vein and the left hepatic vein in fetal life. It is used as a guide and aid to control the left hepatic vein extrahepatically during surgery. By dividing the ligament close to its insertion into the left hepatic vein and retracting it laterally, the angle between the left and the middle hepatic veins, required for dissection and control of the left hepatic vein, may be accessed.

**Porta hepatis, hepatoduodenal ligament and hilar plate**

The porta hepatis is a deep fissure on the inferior surface of the liver. It is situated between the quadrate lobe in front and the caudate process behind, and contains the portal vein, hepatic artery and hepatic nervous plexuses as they ascend into the parenchyma of the liver, and the right and left bile ducts and some lymph vessels as they emerge from the liver. The hepatic ducts lie anterior to the portal vein and its branches, and the hepatic artery with its branches lies between the two (Fig. 68.7). All these structures are enveloped in the perivascular fibrous capsule, the hepatobiliary capsule of Glisson, a sheath of loose connective tissue which surrounds the vessels as they course through the portal canals in the liver and is also continuous with the fibrous hepatic capsule. The dense aggregation of vessels, supporting connective tissue, and liver parenchyma just above the porta hepatis is often referred to as the ‘hilar plate’ of the liver (Fig. 68.8). Understanding of the concept of hilar plate is important in surgical approaches to the hilar structures. Division or lowering of the hilar plate are essential for surgical access to the left hepatic duct. The hepatic artery, bile duct and portal vein extend from the porta hepatis towards the duodenum in the free edge of the hepatoduodenal ligament, which forms the anterior boundary of the epiploic foramen. Rapid control of the vessels entering the porta hepatis can be obtained by dividing the lesser omentum to the left of these structures and passing a tape around them from left to right through the epiploic foramen (a ‘Pringle’ manoeuvre).
Fig. 68.7 Cross-section of the structures at the porta hepatis.
The left hepatic duct remains extrahepatic as it runs down to the bifurcation along the base of segment IV (the quadrate lobe). This extrahepatic length of duct is particularly useful when performing high biliary duct reconstructions where a length of jejunum is anastomosed to form a biliary-enteric bypass, to treat strictures of the common hepatic duct.

**Glisson's sheath**

Glisson's capsule condenses around the branches of the portal triad structures as Glissonian sheaths as they enter the liver parenchyma and extends as far the individual segments of the liver. This arrangement facilitates surgical control of both the main right and left pedicles of the liver as well as all the structures (biliary, autonomic and lymphatic elements) that supply individual sectors and segments in liver complex resectional surgery.
VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The vessels connected with the liver are the portal vein, hepatic artery and hepatic veins. The portal vein and hepatic artery ascend in the lesser omentum to the porta hepatis, where each bifurcates. The hepatic bile duct and lymphatic vessels descend from the porta hepatis in the same omentum (Figs 68.7 and 68.8). The hepatic veins leave the liver via its posterior surface and run directly into the inferior vena cava.

Hepatic artery

In adults the hepatic artery is intermediate in size between the left gastric and splenic arteries. In fetal and early postnatal life it is the largest branch of the coeliac axis. The hepatic artery gives off right gastric, gastroduodenal and cystic branches as well as direct branches to the bile duct from the right hepatic and sometimes the supraduodenal artery (Fig. 68.9A). After its origin from the coeliac axis, the hepatic artery passes anteriorly and laterally below the epiploic foramen to the upper aspect of the first part of the duodenum. It may be subdivided into the common hepatic artery, from the coeliac trunk to the origin of the gastroduodenal artery, and the hepatic artery ‘proper’, from that point to its bifurcation. It passes anterior to the portal vein and ascends anterior to the epiploic foramen between the layers of the lesser omentum. Within the free border of the lesser omentum the hepatic artery is medial to the common bile duct and anterior to the portal vein. At the porta hepatis it divides into right and left branches before these run into the parenchyma of the liver. The right hepatic artery usually crosses posterior (occasionally anterior) to the common hepatic duct (Fig. 68.9B). This close proximity often means that the right hepatic artery is involved in bile duct cancer earlier than the left hepatic artery. Occasionally the right hepatic artery crosses in front of the common bile duct and may be injured in surgery of the common bile duct. It almost always divides into an anterior branch supplying segments V and VIII, and a posterior branch supplying segments VI and VII. The anterior division often supplies a branch to segment I and the gallbladder. The segmental arteries are macroscopically end-arteries although some collateral circulation occurs between segments via fine terminal branches.
A small number of normal variants are important to demonstrate angiographically because they may influence surgical and interventional radiological procedures. A vessel that supplies a lobe in addition to its normal vessel is defined as an accessory artery. A replaced hepatic artery is a vessel that does not originate from an orthodox position and provides the sole supply to that lobe. Rarely a replaced common hepatic artery arises from the superior mesenteric artery (Fig. 68.10) and is identified at surgery by a relatively superficial portal vein (reflecting the absence of a common hepatic artery that would normally cross in front of the vein). More commonly a replaced right hepatic artery or an accessory right hepatic artery arises from the superior mesenteric artery (Fig. 68.11). In this case they run behind the portal vein and bile duct in the lesser omentum and can be identified at surgery by pulsation behind the portal vein. The accessory right hepatic artery may be injured during
resections of the pancreatic head because the artery lies in close proximity to the portal vein. Occasionally, a replaced left hepatic artery or an accessory branch arises from the left gastric artery: these vessels provide a source of collateral arterial circulation in cases of occlusion of the vessels in the porta hepatis but may also be injured during mobilization of the stomach as it lies in the upper portion of the lesser omentum. Rarely, accessory left or right hepatic arteries may arise from the gastroduodenal artery or aorta. The presence of replaced arteries can be lifesaving in patients with bile duct cancer: because they are further away from the bile duct they tend to be spared from the cancer, making excision of the tumour feasible. Knowledge of these variations is also important in planning whole and split liver transplantation.

Fig. 68.10 Most common variants of the main hepatic artery.
Variations in the intrahepatic arteries are common and may be surgically important. For example, the segment VI artery most commonly arises from the left hepatic artery, but in about 10–20% of cases it arises from the right hepatic artery or the main hepatic artery. Failure to recognize this variation may compromise the blood supply to segment IV following right hepatectomy, and is especially important following right lobe donation for live donor liver transplantation.

**Veins**

The liver has two venous systems. The portal system conveys venous blood from the majority of the gastrointestinal tract and its associated organs to the liver (see Ch. 60). The hepatic venous system drains blood from the liver parenchyma into the inferior
vena cava.

**Portal vein**

The portal vein begins at the level of the second lumbar vertebra and is formed from the convergence of the superior mesenteric and splenic veins (Fig. 68.12; see also Fig. 71.4 and Fig. 60.8). It is approximately 8 cm long and lies anterior to the inferior vena cava and posterior to the neck of the pancreas. It lies obliquely to the right and ascends behind the first part of the duodenum, the common bile duct and gastroduodenal artery. At this point it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum, ascends anterior to the epiploic foramen to reach the right end of the porta hepatis and then divides into right and left main branches which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum the portal vein lies posterior to both the common bile duct and hepatic artery. It is surrounded by the hepatic nerve plexus and accompanied by many lymph vessels and some lymph nodes.
The main extrahepatic tributaries of the portal vein are the coronary or the left gastric vein, which ends in the left margin of the portal vein, and the posterior superior pancreatoduodenal vein nearer to the head of the pancreas. The portal vein divides into right and left branches at the hilum (Fig. 68.13). The left portal vein has a longer extraparenchymal course (4–5 cm) and tends to lie slightly more horizontally than the right portal vein, but is often of smaller calibre. It has horizontal and vertical portions. The horizontal portion runs along the base of segment VI and often gives branches to segment I and sometimes to segment VI in this part of its course. The branch to segment II continues laterally but the main left portal vein takes a more anterior and vertical course in the umbilical fissure (the vein of the umbilical fissure) where it gives branches to segments III and IV and receives the obliterated left umbilical vein (ligamentum teres). The majority of the supply to segment IV comes from the left portal vein, and only occasionally from the right via proximal branches of the main vein or branches from veins to segments V or VIII. The right portal vein is only 2–3 cm in length and usually divides into a right medial (anterior) sectoral division supplying segments V and VIII, and a right lateral (posterior) sectoral division supplying segments VI and VII. The medial division may give a branch to segment I.
Variations usually involve the right portal vein: absence of a right portal vein with the resulting portal trifurcation in the form of left portal vein, right medial and right lateral portal veins, is present in 10–15% of livers. Occasionally the right medial vein arises from the left portal vein, a variant which is important to remember during left sided liver resection. The portal trifurcation has implications for split liver and live donor liver transplantation, where its presence might be considered as a relative contra-indication. On rare occasions, the portal bifurcation is absent, in which case the main portal vein enters the liver giving off the right segmental branches and then turns left to supply the left lobe of the liver (a contraindication to major liver surgery). Occasionally one or more of the segmental branches of the right lobe (especially segment IV) arises proximally.

**Porto-systemic shunts**

Increased pressure within the portal venous system may result in dilatation of the portal venous tributaries: a reversal of flow may occur where these veins form anastomoses with veins which drain into the systemic venous circulation. The common sites where porto-systemic shunts may occur, and the associated clinical implications, are listed in Table 68.1.

Hepatic veins

The liver is drained by three major hepatic veins into the suprahepatic part of the inferior vena cava and a multitude of minor hepatic veins that drain into the intrahepatic inferior vena cava. The three major veins are located between the four major sectors of the liver (Figs 68.6A, 68.14 and 68.15).

**Fig. 68.14** Sagittal ultrasound of the middle hepatic vein. Middle hepatic vein draining into the inferior vena cava.
Right hepatic vein

This is the longest and the largest vein and also the most variable. It is usually single, but occasionally it remains as two trunks until it terminates by draining into the inferior vena cava. The right hepatic vein runs into the intersectoral plane between the right medial and right lateral sectors. It drains the whole of segments VI and VII and parts of segments V and VIII. The extent of its contribution to the drainage of segments V and VIII is variable, and depends upon the size of the veins that drain these segments into the middle hepatic vein. The right hepatic vein is formed near the anterior and inferior edge of the liver and lies in a coronal plane through most of its course. It drains into the inferior vena cava near the upper border of the caudate lobe. Of all the three major veins the right hepatic vein is the one which is the most variable in its size not only due to the differential contribution to segments V and VIII drainage along with the middle hepatic vein but also due to the occasional presence of an accessory right middle and right inferior veins.

Middle hepatic vein

The middle hepatic vein lies along the plane between the right medial and the left
medial sectors of the liver. It usually joins with the left hepatic vein and terminates into the inferior vena cava as a common trunk. It drains the central part of the liver receiving constant branches from segments IV, V and VIII. The sizes of the branches draining segments V and VIII are variable and are of surgical importance in terms of right lobe living donation.

*Left hepatic vein*

The left hepatic vein lies between the left medial and left lateral sectors of the liver. It drains segments II, III and occasionally IV. Small veins draining segment II and occasionally the superior part of segment IV may drain directly into the inferior vena cava in the minority of livers. Usually a major tributary of the left hepatic vein, the umbilical fissure vein runs in the intersegmental plane between segments III and IV and contributes to their drainage. Occasionally the vein draining segment III ends separately in the confluence of the left and middle hepatic veins. These variations in the venous drainage are of significance in terms of split liver transplantation and live donor liver transplantation.

*Minor veins*

Segment I veins drain directly into the inferior vena cava and vary in number from one to five. Since it has an independent drainage from the rest of the liver in patients with Budd–Chiari syndrome, where all the major hepatic veins are blocked, segment I often continues to drain effectively and undergoes compensatory hypertrophy. Rarely there is an accessory right middle or inferior hepatic vein. When they are present they are of surgical importance especially if they are of more than 5 mm in diameter; they drain segments V and VI independently of the three major veins and therefore any tumour involving the three major veins can be safely resected as long as venous drainage from the accessory veins is ensured. In live donor and split liver transplantation these veins must be individually anastomosed to the recipient inferior vena cava to ensure adequate venous drainage.

*Transjugular intraparenchymal porto-systemic shunt (TIPS) procedure for portal hypertension*

In extreme cases of chronic portal hypertension, large calibre anastomoses between portal and systemic circulations may be formed within the liver parenchyma using a balloon catheter, introduced via the internal jugular vein and under radiological control, to puncture across and rupture through a thinned strip of liver parenchyma between hepatic veins and dilated portal branches.

*Lymphatics*

Lymph from the liver has abundant protein content. Lymphatic drainage from the liver is wide and may pass to nodes above and below the diaphragm. Obstruction of the hepatic venous drainage increases the flow of lymph in the thoracic duct. Hepatic collecting vessels are divided into superficial and deep systems.

*Superficial hepatic vessels*

The superficial vessels run in subserosal areolar tissue over the whole surface of the liver and drain in four directions. Lymph vessels from the majority of the posterior
